Marin Castaño, Maria E., J. Oost P. Schanstra, Christophe Hirtz, João B. Pesquero, Christiane Pecher, Jean-Pierre Girolami, and Jean-Loup Bascands. B₂ kinin receptor upregulation by cAMP is associated with BK-induced PGE₂ production in rat mesangial cells. Am. J. Physiol. 274 (Renal Physiol. 43): F532–F540, 1998.—In the rat mesangial cell (MC), activation of the bradykinin B₂ receptor (B₂R) by bradykinin (BK) is associated with both phospholipase C (PLC) and A₂ (PLA₂) activities and with inhibition of adenosine 3',5'-cyclic monophosphate (cAMP) formation leading to cell contraction. Because cAMP plays an important role in the regulation of gene expression in general, we investigated the effect of increasing the intracellular cAMP concentration ([cAMP]) in mesangial cells on the B₂ mRNA expression, on the density of B₂ receptor binding sites, on the BK-induced increase in both the free cytosolic Ca²⁺ concentration ([Ca²⁺]), and in the prostaglandin E₂ (PGE₂) production. Forskolin, PGE₂, and cAMP analog, 8-bromoadenosine 3',5'-cyclic monophosphate (8-Br-cAMP), were used to increase [cAMP]. Twenty-four-hour treatment with forskolin, PGE₂, and 8-Br-cAMP resulted in significant increases in B₂ receptor binding sites, which were inhibited by cycloheximide. The maximum B₂ receptor mRNA expression (160% above control) was observed in cells treated during 24 h with forskolin and was prevented by actinomycin D. In contrast, the d-myo-inositol 1,4,5-trisphosphate (IP₃) formation and the BK-induced increase in [Ca²⁺], reflecting activation of PLC, were not affected by increased levels of [cAMP]. However, the BK-induced PGE₂ release, reflecting PLA₂ activity, was significantly enhanced. These data bring new information regarding the dual signaling pathways of B₂ receptors that can be differentially regulated by cAMP.

bradykinin; B₂ kinin receptor messenger ribonucleic acid; prostaglandin E₂; free cytosolic calcium; adenosine 3',5'-cyclic monophosphate; mesangial cell

THE NONAPEPTIDE BRADYKININ (BK) is a potent vasoactive peptide generated by the proteolytic action of serine proteases called kallikreins, acting on protein precursors named kininogens, present in plasma and tissue (6). In plasma, the half-life of kinins is 15–20 s, and their concentrations in biological fluids are in the femtomolar range, far below the affinity of any identified bradykinin receptor. Therefore, it is likely that BK has to be generated very close to its site of action. Pharmacological studies have demonstrated that kinins exert their biological effects through the activation of at least two receptors, named the B₁ and B₂ receptors (49). The docking of both receptors has revealed that they belong to the family of seven-transmembrane domain, G protein-coupled receptors. The cDNA coding for the B₁ receptor has been recently cloned and characterized in rabbit, human, and mouse (32, 41, 48). The B₂ receptor cDNA has been cloned from rat (39), mouse (40), and human (24), and the amino acid sequence of the latter was found to be 36% identical to that of the human B₁ receptor. Under physiological conditions, most of the biological effects of kinins are mediated through the B₂ receptor. Indeed, the B₁ receptor is not expressed at significant levels under these conditions, but its expression is strongly induced by cytokines (35). Kinins are involved in a wide range of functions, including systemic and local hemodynamic regulation (regulation of systemic blood pressure and organ blood flow), inflammatory responses, water and electrolyte transport, and pain-transmitting mechanisms (37). BK receptors are expressed at various sites of the nephron and are involved in different effects. In renal microvessels, BK is involved in the regulation of papillary blood flow (37). In the distal collecting tubule, BK is able to reduce the action of arginine vasopressin (AVP) on water reabsorption by inhibiting the AVP-induced increase in cAMP production (37). More recently, we demonstrated the presence of BK receptors in freshly isolated glomeruli and cultured mesangial cells, which are contractile cells and represent about one-third of the glomerular cell population (18). Furthermore, we have reported that the activation of the B₂ receptor on cultured mesangial cells stimulates cell proliferation (5). In mesangial cells, the activation of the B₂ receptor by BK induces the phospholipase C (PLC) and A₂ (PLA₂) pathways leading to cell contraction (3), but it also inhibits cAMP formation (4).

Because mesangial cells express both B₁ and B₂ receptors and may be involved in opposite effects, it is of great interest to define more precisely some aspects of the regulation of B₂ receptor expression. One crucial point concerning the action of BK is that the two receptors can be stimulated by the same agonist BK but with different affinities. Thus examination of the regulation of expression of BK receptors is a prerequisite in the understanding of BK action. At present, the regulation of the B₂ receptor in response to ligand binding or pathological factors has been examined in only a few studies (17, 19, 23, 54), but to our knowledge, no studies have been performed on the regulation of the B₂ receptor at the level of mRNA expression in renal tissue. Experiments on mesangial cells in culture have demonstrated that they respond to a number of vasoactive substances like AVP, angiotensin II, platelet-derived growth factor, adenosine, and endothelin by
contraction, whereas atrial natriuretic factor, dopamine, prostaglandin E₂ (PGE₂), nitric oxide, guanosine 3',5'-cyclic monophosphate (cGMP), and adenosine 3',5'-cyclic monophosphate (cAMP) induce relaxation (for reviews, see Refs. 16, 42, 52). Because a number of these vasoactive factors can stimulate the formation of cAMP in mesangial cells and since a putative cAMP response element (CRE) exists in the 5'-flanking region of the B₂ receptor gene of the rat (46), the present study was designed to determine whether B₂ receptor expression and its related cellular responses are regulated by cAMP in rat mesangial cells. The intracellular cAMP concentration ([cAMP]i) was increased by treatment with forskolin or PGE₂, and the possible functional changes of the B₂ receptor were assessed by measuring the BK-induced increase in free cytosolic calcium and prostaglandin secretion. The data show that elevating the intracellular level of cAMP increases both the expression of B₂ mRNA and the B₂ binding site density, accompanied by an increase in BK-induced prostaglandin secretion. However, no related changes in the BK-induced increase in free cytosolic calcium were observed.

MATERIALS AND METHODS

Materials. Fetal calf serum (FCS), RPMI 1640, and collagenase were from Boehringer. Penicillin, streptomycin, gluta
cine, d-valine, BK, [D-Arg-Hyp₃-D-Phe⁷]BK, cycloheximide, and lysozyme, diethyl pyrocarbonate, and polyethylenimine were purchased from Sigma Chemical (Saint Quentin Fallavier, France). 8-bromoadenosine 3',5'-cyclic monophosphate (8-BrcAMP), PGE₂, indomethacin, sucrose, phenanthrolene, leup
tin, bacitracin, benzamidine, captopril, phosphoramidon, 3-isobutyl-1-methylxanthine, and forskolin were from Boehringer. Rat glomerular mesangial cells were prepared from kidneys of 7-wk-old male Sprague
dawley rats (Iffa Credo, Lyon, France). Glomerular explants were digested in a 12 ml of an ice-cold mixture of methanol and formic acid (4:1) for 15 min at 100°C with 1 M NaOH using the method of Lowry et al. (31), with bovine serum albumin as standard.

Incubation protocols and assays for cAMP. Cultured mesan
gial cells were seeded into six-well culture trays (Nunc) at a density of 5 × 10⁴ cells/well and cultured with the complete medium for 48 h. Before treatment, cells were rendered quiescent by incubation for an additional 24-h period in the same growth medium containing 0.5% FCS. The cells were washed three times with 1 ml/well of phosphate-buffered saline before treatment for 6, 18, or 24 h with forskolin (0.1 µM) or PGE₂ (0.1 µM) in the presence of 0.5 mM IBMX. At the end of the incubation time, the reaction was stopped by removal of the medium, followed immediately by the addition of 1.6 ml of an ice-cold mixture of methanol and formic acid (95%/5%) to each well, so that only intracellular cAMP was measured. After solubilization for 15 min at 100°C with 1 M NaOH using the method of Lowry et al. (31), with bovine serum albumin as standard.

Measurements of d-myo-inositol 1,4,5-trisphosphate. To measure d-myo-inositol 1,4,5-trisphosphate (IP₃) production, mesan
gial cells were treated as described above. The production of IP₃ was assayed as previously described (1). Briefly, at the end of the incubation time (24 h) in the presence of either forskolin (0.1 µM), PGE₂ (0.1 µM), or 8-BrcAMP (100 µM), the culture medium was drawn off, replaced by fresh medium,
and stimulated for 30 s with BK (0.1 µM). The stimulation was stopped by adding 10% perchloric acid followed by incubation on ice for 15 min. After neutralization with ice-cold 1.5 M KOH, the samples were centrifuged at 2,000 g for 15 min at 4°C. The supernatants were kept cold on ice, and aliquots of 100 µl were used to measure the IP3 concentration using the [3H]IP3 RIA kit system (Amersham, Les Ulis, France).

Measurements of intracellular calcium concentration. The intracellular calcium concentration ([Ca2+]i) was determined as currently done in the laboratory and previously described in detail (2, 4). After treatment with 8-BrcAMP (100 µM), forskolin (0.1 µM), or PGE2 (0.1 µM) in the presence of IBMX (0.5 mM) during the indicated time, mesangial cells were washed with Krebs-Ringer buffer containing 10 mM N-2-hydroxyethylpiperazine-N’-2-ethanesulfonic acid (pH 7.4), 145 mM NaCl, 2.5 mM KH2PO4, 1 mM CaCl2, 1 mM MgSO4, 10 mM glucose, and 0.1% bovine serum albumin (BSA), loaded for 45 min in a 5 µM solution of fura 2-AM at 37°C in the presence of 0.1% BSA, and washed twice before measuring the [Ca2+]i in response to BK (from 0.1 nM to 0.1 µM) stimulation. Fluorescence measurements were done using a Spex Fluorolog spectrofluorometer, set for alternative dual-wavelength excitation at 340 and 380 nm. Light emitted at 505 nm was collected by a photomultiplier and passed to a Spex system microcomputer, which averaged the emission collected over a 0.5-s period at each excitation wavelength. Autofluorescence of unloaded cells was found to be ~18% of the emitted signal and was subtracted from the fura 2-loaded fluorescence at each excitation wavelength before calculating the fluorescence ratio R (340/380). As previously described, [Ca2+]i was calculated from the equation of Grynkiewicz et al. (22): [Ca2+]i = Kd × (R – R_min/R_max – R) × λ, where Kd (224 nM) is the dissociation constant of the complex fura 2-Ca2+, and R_min, R_max, and λ are constant parameters depending on the optical system used. Under our experimental conditions, they were R_min = 0.8, R_max = 16, and λ = 4.

Induction of prostaglandin release and measurement. Mesangial cells were treated as described above. At the end of the incubation time in the presence of either forskolin (0.1 µM) or 8-BrcAMP (100 µM), the culture medium was drawn off and replaced by fresh medium containing BK (0.1 µM). The amount of prostaglandins secreted was determined after 5-min incubation at 37°C. After the 5-min incubation with BK, the supernatant was removed, centrifuged at 4,000 g, and the resulting supernatant was stored frozen until assayed for prostaglandins. The amount of PGE2 secreted in the medium was assayed directly by specific EIAs (Cayman Chemical) (3). In brief, this assay is based on the competition between free prostaglandin and acetylcholinesterase-linked prostaglandin for rabbit prostaglandin antiserum. The prostaglandin for rabbit prostaglandin antiserum. The prostaglandin antiserum was coated onto 96-well plates (Nunc certified) via a monoclonal anti-rabbit antibody. The enzymatic tracer (acetylcholinesterase) cleaves the Ellman reagent added to the well, and the colored substance released is inversely proportional to the amount of produced prostaglandin (expressed as picograms secreted during 5-min incubation per million of cells).

RNA isolation and Northern blot analysis. Mesangial cells were treated as described above, and total RNA was extracted as described previously (2). The RNA pellet was dried and dissolved in water containing diethyl pyrocarbonate (0.1%). RNA was quantified by ultraviolet spectrophotometry at 260 and 280 nm. Only RNA preparations with an OD260/OD280 ratio between 1.9 and 2.1 were used for cDNA synthesis. RNA (25 µg) was denatured and separated by electrophoresis on a 1.2% agarose/formaldehyde gel and transferred overnight onto a standard nylon membrane (Hybond-N; Amersham, Les Ulis, France) with 20× SSC (standard sodium citrate) as the transfer buffer. The RNA was fixed to the membrane under ultraviolet radiation (254 nm) in a ultraviolet crosslinker (Stratagene). Membrane filters were prehybridized for at least 4 h at 42°C in a phosphate buffer (pH 6.5) containing 45% deionized formamide, 4× SSC, 5× Denhardt’s reagent (Sigma), 0.1% sodium dodecyl sulfate (SDS), and 7.5 µg/ml of denatured salmon sperm (Sigma)Hybridization was performed overnight at 42°C using hybridization buffer (0.1 M NaH2PO4, pH 6.5, 45% deionized formamide, 4× SSC, 1× Denhardt’s reagent, 0.1% SDS, and 7.5 µg/ml of denatured salmon sperm) and, as a probe, a 1.4-kb fragment corresponding to the coding region of the rat B2 receptor (46), labeled with [α-32P]dCTP by random priming (Amersham Megaprime Kit). The membrane was washed once with 2× SSC/0.1% SDS at room temperature and twice at 65°C for 30 min. Autoradiography was performed for 1–4 days at ~80°C using Amer sham Hyperfilm-MP film with intensifying screens.

After hybridization with the B2 receptor probe and exposure, blots were washed and rehybridized with a β-actin cDNA probe, obtained by polymerase chain reaction, as previously described (2), to control for loading and transfer of total RNA in individual samples. The quantity of B2 receptor and β-actin mRNAs was evaluated by scanning the membrane with a Phosphor imager (Molecular Dynamics) with which the densitometric value of each band was calculated. The B2 receptor mRNA expression was normalized to the densitometric values obtained for the constitutively expressed β-actin mRNA signal.

Statistical analysis. Values are expressed as means ± SE of 3–6 independent experiments. The nonparametric Mann-Whitney U-test was used for comparisons between two unpaired variables. Multiple means were compared using single-factor analysis of variance. Differences were considered significant at P < 0.01 or P < 0.05.

RESULTS

CAMP production in forskolin and PGE2-treated mesangial cells. The effect of forskolin (0.1 µM) and PGE2 (0.1 µM) treatment in the presence of an inhibitor of phosphodiesterase (IBMX, 0.5 mM) for 6, 18, and 24 h on the mesangial cell cAMP content is shown in Fig. 1. Both forskolin and PGE2 treatment increased significantly the cAMP level by three- and twofold, respecti-
Effect of [cAMP]-stimulating agents and 8-Br-cAMP on the density of B<sub>2</sub> binding sites. The presence of B<sub>2</sub> receptors on mesangial cells (5) was verified in binding studies using [125I]-[Tyr<sup>9</sup>]BK. The specificity of the binding was that of a typical B<sub>2</sub> receptor binding site, since the specific B<sub>1</sub> antagonist, des-Arg<sup>9</sup>-Leu<sup>8</sup>-BK, was unable to displace [125I]-[Tyr<sup>9</sup>]BK in competition studies, where the relative order of potency in displacing [125I]-[Tyr<sup>9</sup>]BK binding was HOE-140 > BK > [d(Arg)-Hyp<sup>1</sup>-D-Phe<sup>7</sup>]BK (data not shown). Despite a significant increase in the [cAMP]i after 6 h of treatment with the different cAMP-stimulating agents (Fig. 1), there was a delay before any detectable increase in the B<sub>2</sub> receptor binding site density could be observed (Fig. 2A). As previously described (5), in mesangial cells, the population of binding sites included a small number (B<sub>max</sub> close to 20 fmol/mg protein) of high-affinity sites (K<sub>d</sub> < 1 nM) and a large number (B<sub>max</sub> > 80 fmol/mg protein) with an affinity ~3 nM (Table 1). Whereas the density of the high-affinity BK binding sites was not affected (Table 1) by the chronic treatment with forskolin (0.1 µM), PGE<sub>2</sub> (0.1 µM), and 8-Br-cAMP (100 µM), the density of the low-affinity population of BK binding sites was significantly increased after 24 h of treatment (Fig. 2A). After 24-h treatment, B<sub>max</sub> values were 89 ± 9, 148 ± 11, 125 ± 10, and 131 ± 7 fmol/mg protein for the control, forskolin, PGE<sub>2</sub>, and 8-Br-cAMP-treated mesangial cells, respectively. The receptor affinity was unchanged and remained in the nanomolar range (Table 1). Moreover, the effect of 24-h treatment with [cAMP]-elevating agents on the density of the low-affinity BK binding sites was dose dependent, as shown in Fig. 2B. Furthermore, the increase in B<sub>2</sub> receptor binding site density induced by 24-h treatment with forskolin, PGE<sub>2</sub>, or 8-Br-cAMP was completely inhibited with the protein synthesis inhibitor cycloheximide (CHX, 5 µg/ml, Fig. 2C).

Effect of [cAMP]-stimulating agents on B<sub>2</sub> receptor mRNA expression. Northern blot analysis of total RNA from primary cultured rat mesangial cells using a B<sub>2</sub> receptor probe demonstrated the presence of a 4.2-kb band, which is in agreement with the expected size for B<sub>2</sub> receptor mRNA (Fig. 3A). When the results were normalized by calculating the ratio B<sub>2</sub>/β-actin, a significant increase in B<sub>2</sub> receptor mRNA was observed in forskolin-treated cells for 18 and 24 h and PGE<sub>2</sub>-treated cells for 24 h (Fig. 3B). The strongest increase was observed in forskolin-treated cells for 24 h, where the increase in B<sub>2</sub> receptor mRNA expression (Fig. 5).
BK induces a rapid and transient release of IP$_3$ with a peak value after 30 s of BK stimulation (1). To verify whether the cAMP-induced increase of B$_2$ receptor number had any effect on BK-induced conversion of phosphatidylinositol 4,5-bisphosphate by PLC to IP$_3$, we measured IP$_3$ production after 24 h of forskolin (0.1 µM), PGE$_2$ (0.1 µM), and 8-BrcAMP (100 µM) treatment. No clear differences were observed. In control cells, IP$_3$ production increased from 52 ± 5 to 165 ± 13 pmol/mg protein on stimulation with BK (0.1 µM). After treatment with forskolin, PGE$_2$, or 8-BrcAMP, IP$_3$ production increased from 49 ± 7 to 176 ± 16 pmol/mg protein on BK stimulation (0.1 µM).

Effect of 8-BrcAMP and [cAMP]-stimulating agents on the BK-induced intracellular calcium increase. As shown in Fig. 6A, addition of BK (0.1 µM) to adherent mesangial cells induced a rapid and transient rise in [Ca$^{2+}$i], reaching a peak value which then declined to a stable resting level (plateau). Treatment with either forskolin (0.1 µM), PGE$_2$ (0.1 µM), or 8-BrcAMP (100 µM) for 6, 18, or 24 h did not significantly modify either the basal free cytosolic calcium or the mobilization (transient and sustained phases) of [Ca$^{2+}$i] induced by 0.1 µM BK (Table 2, Fig. 6B). As previously described (5), the effect of BK on the [Ca$^{2+}$i] was dose dependent (Table 2). Neither the basal [Ca$^{2+}$i] nor the dose-dependent increase in [Ca$^{2+}$i] in response to BK in the range from 0.1 nM to 0.1 µM was affected by the treatment with forskolin, PGE$_2$, or 8-BrcAMP (Table 2).

Effect of 24 h forskolin and 8-BrcAMP treatment on BK-induced prostaglandin release. Because activation of the B$_2$ receptor by BK is also known to stimulate the PLA$_2$ pathway (9), we have examined the effect of BK on the PGE$_2$ production. In untreated mesangial cells, BK (0.1 µM) increased the basal value from 285 ± 35 to 2,842 ± 230 pg PGE$_2$·5 min$^{-1}$·1 million cells$^{-1}$ (Fig. 7). The BK stimulation of cells pretreated with either forskolin (0.1 µM) or 8-BrcAMP (100 µM) for 24 h induced a further increase of, respectively, 4,253 ± 310 and 4,052 ± 286 pg PGE$_2$·5 min$^{-1}$·1 million cells$^{-1}$. The increase in BK-induced PGE$_2$-secretion observed

Data show ratios of densitometric values of B$_2$ receptor to β-actin. Each is expressed in % of control value (100%) for each incubation time. *P < 0.05, compared with respective control.
in cells treated with forskolin or 8-BrcAMP was abolished by indomethacin (1 µM) but not by the PLC inhibitor U-73122 (0.5 µM) added during the 5-min incubation period with BK (not shown).

DISCUSSION

In the present study, we focused our attention to the relationship between the cAMP-induced stimulation of the expression of the B2 receptor and its related cellular responses. We have demonstrated that, in primary culture of rat mesangial cells, agents increasing the intracellular cAMP levels also increase B2 receptor mRNA levels, as well as the B2 receptor density. Furthermore, actinomycin D, a transcriptional inhibitor, and cycloheximide, a protein synthesis inhibitor, completely inhibited the cAMP-induced rises in B2 mRNA and B2 receptor binding. We have also examined whether this increase in B2 receptor density modified its related transduction pathways. Whereas the increase in mRNA level and binding sites were accompanied by an increase in the BK-stimulated release of PGE2, no effect on BK-induced IP3 production and calcium second messenger production was observed. Therefore, these data bring new information regarding the dual signaling pathways of B2 receptors observed in various cell types.

The effect of cAMP on BK receptor density and on BK-induced signal transduction has been investigated (14, 15, 20, 36), and conflicting results were reported depending on the cell type studied and on the duration of treatment with agents that increase the intracellular cAMP concentration. In human fibroblasts, Etscheid et al. (20) have reported that cholera toxin, pertussis toxin, and forskolin induced a fourfold increase in the number of BK receptors associated with an enhanced arachidonic acid release in response to BK, which is in good agreement with our results. In human tracheal epithelial cells (14), very short-term pretreatment (5 min) with isoproterenol, which is known to increase the cAMP concentration, did not affect the calcium response to BK, indicating only that cAMP did not interfere with the BK-induced increase in [Ca2+]i in this cell type. In canine tracheal smooth muscle cells (TSMC), long-term (24 h), but not short-term (<4 h), treatment with agents that increase intracellular cAMP enhanced both BK receptor binding and BK-induced increases in inositol phosphates and intracellular cal-

cium (36). However, Mao Yang et al. (36) used a 100-fold higher dose of forskolin than the one we determined as having the maximum cAMP-releasing capacity. Another likely explanation is that the control TSMC partially lost their BK receptors or have a much lower receptor density than in mesangial cells. Although pretreatment with 10 µM forskolin for 24 h in these studies (36) induced an eightfold increase in BK-binding sites, the stimulated [Ca^{2+}]_i level was similar to the level we have observed in mesangial cells before challenging the cAMP production. A similar increase in B2 receptor synthesis was evoked, by increasing the [cAMP], in rat arterial smooth muscle cells (15). However, the increase in B2 receptor synthesis was determined using binding analysis, and the receptor mRNA level was not examined. Moreover, in this study, the author shows that only long-term stimulation with cAMP (24 h) enhanced both BK binding sites and BK-stimulated calcium mobilization, whereas short-term stimulation with cAMP produced a variable inhibition of BK-stimulated calcium mobilization, depending on the passage number of the cells (15). In these studies, a 200-fold higher dose of forskolin (20 µM) was used. Finally, in contrast to previous work on mesangial cells (44), including our present data, Dixon (15) observed a very small effect of PGE2 treatment on the increase of [cAMP], without any effect on the number of BK receptor binding sites (15).

Most of the studies, except those of Etscheid et al. (20), describe only the changes in the cellular responses of BK by its effect on [Ca^{2+}]_i mobilization. Indeed, it has been hypothesized for a long time that BK mediated all its cellular responses through PLC activation and that stimulation of PLA2 was considered as a PLC-dependent mechanism. The lack of increase in [Ca^{2+}]_i following chronic cAMP treatment seems to be specific for the BK transduction pathway, since we observed a decrease in [Ca^{2+}]_i mobilization in response to angiotensin II (0.1 µM) after 24 h treatment with forskolin (data not shown). Such a phenomenon was also observed in rat arterial smooth muscle cells (15). Interestingly, our data show that only the low-affinity population of BK receptors was increased by agents that increase the intracellular cAMP level and that this was accompanied by an enhanced release of PGE2 induced by BK, suggesting that the newly synthesized receptors are principally coupled to the PLA2 signaling pathway. This is supported by the observation that BK-induced PGE2 production was inhibited by PLA2 inhibitor indomethacin but not by PLC inhibition by U-73122. These data are consistent with previous studies showing that BK-induced activation of PLC and PL A2 are partly independent (9, 25). In addition, we have previously demonstrated that BK induced contraction via two independent mechanisms, one associated with the PLC pathway and one dependent on prostaglandin formation (3).

This selective coupling of the newly synthesized, low-affinity B2 receptors might be explained by the existence of multiple-affinity states of G protein-coupled receptors (8, 11, 51). These multiple-affinity states are thought to be regulated by binding of different G proteins (8, 11, 51) and/or by phosphorylation of Ser/Thr residues on the receptor occurring after activation of the human B2 receptor (7). Furthermore the B2 receptor was shown to couple at least to three different G proteins (29, 30). In this context, it is interesting to note that there is clearly one B2 receptor mRNA (Refs. 24, 39, 40, this work), but several groups have reported two BK binding sites (28, 34, 45).

cAMP is involved in the up- or downregulation of receptor expression of some vasoactive agents, such as angiotensin II (12, 13, 33) and endothelin (43), in various cell types. A well-known mechanism, whereby cAMP regulates gene transcription, involves the phosphorylation by protein kinase A and subsequent activation of transcription factor CREB, the CRE binding protein, which binds to the CRE located in the 5'-untranslated region of these genes (50). We found that increased intracellular concentration of cAMP induced B2 receptor mRNA expression. This result is consistent with the presence of a CRE located in the promoter region of the B2 receptor gene in rat (46). Indeed, a recent study of Pesquero et al. (47) showed that part of the B2 receptor promoter region containing the CRE (a 1-kb fragment) induced reporter gene activity on treatment with the cAMP analog, 8-Br-cAMP. Although these and our data do not exclude the possibility of a stabilizing effect of cAMP on B2-mRNA, they favor induction of transcription by cAMP.

It is now well admitted that glomerular mesangial cells increase their intracellular cAMP concentration in response to a wide spectrum of humoral agents like parathyroid hormone, arginine vasopressin, serotonin, histamine, prostaglandins, and isoproterenol (for reviews, see Refs. 16, 42). Glomerular diseases are associated with mesangial cell dysfunctions, such as alteration in cell contraction, cell proliferation, and matrix secretion (26), where cyclic nucleotides play an important role. Therefore, the physiological significance of the present results should be related to pathological states like glomerular inflammation. In these situations, mesangial cells are both producers of and targets for a variety of cytokines, eicosanoids, and reactive oxygen species. All these inflammatory agents mediate part of their cellular effects by stimulating cAMP and cGMP production. Furthermore, it has been shown that, in glomeruli, accumulation of cyclic nucleotides is higher than in renal tubules (53). Moreover, cAMP and cGMP accumulation can also result from a decreased activity of their degradation pathway involving phosphodiesterase (PDE). Although PDE activity has not been extensively investigated in renal diseases, a decrease in PDE activity was recently reported in rat with unilateral obstruction (38). In this respect, the increase in functional B2 receptor by an increased cAMP concentration only associated with the increase in PGE2 production is of potential interest. Indeed, although the major described function of PGE2 in the glomerulus is the maintenance of glomerular filtration by counteracting the effects of vasoconstrictive peptides (42), other important effects have been assigned to PGE2. It has been
demonstrated that PGE2 inhibits growth of mesangial cells via the inhibition of MAP kinase (55) and that PGE2 reduces the expression and secretion of collagen (56).

In conclusion, we provide new evidence that expression of a G protein-coupled receptor can be upregulated by cAMP not only at the level of the receptor expression but also at the level of the second messenger pathway. Finally, the selective stimulating effect of cAMP on BK-induced PGE2 secretion through stimulation of B2 receptor expression provides strong evidence for the existence of a dual and independent signaling pathway of this receptor, although the coupling mechanism remains to be investigated.
