LITHIUM (Li) has been in clinical use for about half a century, mostly for the treatment of bipolar disorder, which affects up to 2% of the US population (33), with double the incidence in veterans. Mental depression and substance abuse, which are often encountered in posttraumatic stress disorder patients, such as war veterans, are known to predispose them to bipolar disorders. Despite the advent of newer drugs for bipolar disorders, Li is still an important medication in the psychiatric treatment regimen by virtue of the significantly lower suicidal risk in Li-treated patients (3). In addition, the advances in the pharmacotherapeutics of bipolar disorder over the past 10–15 yr have been predominantly in terms of tolerability and safety, with no new treatments being demonstrated to be more effective than Li (38). Furthermore, recent studies unraveled the neuroprotective effect of Li, thus making it a potential drug for the treatment of acute brain injury (e.g., stroke or ischemia), as well as chronic neurodegenerative diseases, such as Alzheimer, Parkinson, and Huntington diseases (12, 35, 45, 53).

Whether it is for bipolar disorder or chronic neurodegenerative diseases, Li therapy is administered for long durations. However, therapeutic use of Li is often limited because of its adverse side effects on the kidney. In the clinic, patients on Li therapy often present with classical symptoms of nephrogenic diabetes insipidus (NDI), which include polyuria, polydipsia, and reduced ability to concentrate urine and a lack of response to arginine vasopressin (AVP) administration (18). In animal models, Li-induced polyuria is associated with decreased protein abundance of AVP-regulated collecting duct water channel aquaporin (AQP)2 (31, 36). The AVP resistance in Li-induced NDI has been attributed to increased production of renal prostaglandin (PG)E2 (48). PGE2 is a potent antagonist of AVP action on collecting duct (19, 40, 44, 56). Administration of indomethacin, which inhibits PGE2 biosynthesis, ameliorates the polyuric condition, thus confirming the involvement of PGE2 in the Li-induced polyuria (2).

NDI is a debilitating condition that can result in severe fluid and electrolyte imbalance, especially in elderly patients, who exhibit impaired thirst mechanism (29, 34). Dehydrated NDI patients can develop hypernatremia, alterations in the level of consciousness, and hemodynamic instability from hypovolemia. Currently used therapeutic modalities, such as the combined use of a thiazide with a potassium-sparing diuretic (amiloride) or prostaglandin synthesis inhibitor (indomethacin or other cyclooxygenase inhibitors), are encountered with varying degrees of success as well as side effects, including Li intoxication (39, 41). Replacement of the current side effect-prone therapies with new drugs based on an improved understanding of molecular pathophysiology of Li-induced NDI should result in improved efficacy and fewer side effects.

One potential approach for the development of new therapies could be to decrease the production of renal PGE2, if we can identify the driving force(s) for the increased production of PGE2 by medullary collecting ducts in Li-induced NDI. In this context, we previously identified (54) that extracellular nucleotides (ATP/UTP), presumably acting through purinergic P2y2 receptor in normal rat medullary collecting duct, induce production and release of PGE2. We also reported (49) that this phenomenon is markedly enhanced in sucrose water-induced polyuria and blunted in the dehydrated condition. Hence, we hypothesized that purinergic signaling may play a key role in
the pathogenesis of Li-induced NDI by enhancing the production of PGE₂ by medullary collecting ducts and thus leading to a vasopressin-resistant state. In this study, using multiple approaches that involve ex vivo nucleotide-stimulated production of PGE₂ by medullary collecting ducts, determination of expression of mRNA of P₂y receptor subtypes in the inner medulla by quantitative RT-PCR, and confocal laser immunofluorescence localization of P₂y₂ and P₂y₄ receptor proteins in the inner medulla, we document that enhanced purinergic signaling in medullary collecting duct of Li-fed rats may potentially contribute to NDI.

METHODS

Experimental animals. The animal protocols involved in these studies were approved by the Institutional Animal Care and Use Committees of the Department of Veterans Affairs Salt Lake City Health Care System and the University of Utah. Specific pathogen-free male Sprague-Dawley rats were purchased from Charles River Laboratories (Wilmington, MA).

Li-induced NDI model. Groups of rats were fed either a normal rat chow (control diet) or normal rat chow with added Li chloride (40 mmol/kg chow) with free access to drinking water for 14 or 21 days. Both diets were custom prepared by MP Biomedicals (Aurora, OH). Twenty-four-hour urine output and water intake were monitored before the experimental period, periodically during the Li feeding, and before euthanasia. At the end of the experimental period rats were euthanized by pentobarbital sodium overdose. Urine, blood, and kidney tissue samples were collected for analysis. Serum levels of Li were assayed on an automated clinical chemistry analyzer. Urine, blood, and kidney tissue samples were collected for analysis. Serum levels of Li were measured by vapor pressure method on an osmometer were assayed on an automated clinical chemistry analyzer. Serum levels of Li were measured by vapor pressure method on an osmometer.

Measurement of nucleotide-stimulated release of PGE₂ by medullary collecting ducts. Fractions enriched in medullary collecting ducts were prepared and assayed for nucleotide-stimulated PGE₂ release by the methods established in our laboratories (49, 50). Briefly, freshly obtained inner medullas from control or Li-added diet-fed rats (n = 5 rats in each group) were digested by collagenase and hyaluronidase, followed by low-speed centrifugation and washings to separate the inner medullary collecting ducts from non-inner medullary collecting duct elements. The inner medullary collecting duct suspensions thus obtained were challenged with nucleotides. PGE₂ released into the medium was assayed with an EIA kit (Cayman Chemical) after the medullary collecting ducts were pelleted by centrifugation. The values obtained for PGE₂ in the incubations were normalized to the protein contents of the respective pellets. Protein was quantified by using a Coomassie Plus Protein Assay Reagent Kit (Pierce Biotechnology, Rockford, IL).

Quantitative real-time RT-PCR assays on inner medullary samples. This was performed as described previously with minor modifications (28, 50). Briefly, total RNA from the inner medullas of control or Li-added diet-fed rats (n = 4 rats in each group) was isolated by the TRizol method (Invitrogen, Carlsbad, CA), according to manufacturer’s recommendations. Traces of genomic DNA in the extracted RNA samples were digested by DNase treatment (DNase I, amplification grade, Invitrogen), followed by the inactivation of DNase by EDTA. cDNA was synthesized by reverse transcription with SuperScript III First-Strand Synthesis SuperMix (Invitrogen). cDNA was quantified by real-time amplifications on the Applied Biosystems 7500 Fast Real-Time PCR System (Foster City, CA) with SYBR Green PCR Master Mix and AmpliTaq Gold. Table 1 shows the nucleotide sequences of the primer pairs used in PCR. The DNA was amplified for 40 cycles by setting the annealing temperature to 60°C. Specificity of amplifications was determined by sequencing PCR products. The expression of P₂y₁, P₂y₂, P₂y₄, and P₂y₆ receptors was computed relative to the expression of the housekeeping gene β-actin.

Immunofluorescence confocal microscopy of inner medullas. This was performed per the methods established in our laboratories (11, 21). Briefly, formalin-fixed and paraffin-embedded kidney sections (20-μm thickness) from control or Li-added diet-fed rats (n = 4 rats in each group) were deparaffinized, rehydrated, and treated with Dako Antigen Retrieval reagent (Dako Cytomation, Carpinteria, CA). The sections were then permeabilized by Triton X-100 treatment, followed by incubation with Image-iT FX Signal Enhancer (Molecular Probes, Carlsbad, CA). Rabbit polyclonal antibodies to P₂y₂ or P₂y₄ were used in conjunction with Cy5-conjugated donkey anti-rabbit IgG (Jackson ImmunoResearch, West Grove, PA). P₂y₂ receptor antibody was raised and characterized by us (27, 28). It is directed to a COOH-terminal peptide sequence. P₂y₆ receptor antibody was purchased from Novus Biological (Littleton, CO). According to the manufacturer, it was raised against the first cytoplasmic domain of human P₂y₆ receptor, which has 67% rat identity and 80% rat homology. Nuclei were stained with propidium iodide. Confocal laser microscopy was performed with a Nikon E800 upright microscope with Pan Fluor oil immersion lenses. A Simple Personal Confocal Image program (PCI, Compix, Cranberry Township, PA) was used to acquire digital images. Cy5 was detected with a red HeNe laser at 633 nm.

P₂y₂ receptor primer sequences are as published by us previously (28, 50). Primer pairs for other P₂y receptors were based on the sequences published by Wildman et al. (55).
Statistical analysis. Quantitative data are expressed as means ± SE. Differences between the means of two groups were analyzed by unpaired t-test. Differences among the means of more than two groups were analyzed by analysis of variance (ANOVA), followed by the assessment of differences by Tukey-Kramer multiple-comparison test. P values <0.05 were considered significant.

RESULTS

Characterization of rat model of Li-induced NDI. We have chosen a diet containing 40 mmol of Li chloride per kilogram of food because this concentration of Li when fed to rats up to 4 wk was shown to induce NDI in animals, mimicking the clinical condition seen in patients, without causing overt Li toxicity (31). Figure 1 shows the characterization of this Li model with respect to polydipsia and polyuria. Compared with the rats on regular diet, Li-fed rats showed 1) statistically significant smaller increases in body weight (Fig. 1A); 2) approximately twofold increase in water consumption (Fig. 1B); 3) two- to threefold increase in urine output (Fig. 1C); and a comparable threefold decrease in urine osmolality (Fig. 1D) on days 14 and 21. The severe polydipsia and polyuria in Li-fed rats were associated with marked decreases in protein abundance of AVP-regulated water channel AQP2 in inner medulla. The abundance of 29-kDa native AQP2 protein molecule in Li-fed rats decreased to ~20% of that in the control group, whereas the abundance of glycosylated forms of AQP2 (35–50 kDa) was decreased to ~15% of the control group on day 21 (Fig. 2). The decrease in the observed changes in the parameters studied here are quite comparable to the results published by other investigators using a similar regimen of Li feeding (31, 36). Furthermore, Li levels in the blood of rats fed Li-added diet were 1.11 ± 0.07 (n = 8) and 1.18 ± 0.05 (n = 8) mmol/l after 14 and 21 days, respectively. These values are within the therapeutic range seen in patients on Li therapy (0.5–1.5 mmol/l). Thus our model mimics the clinical condition of Li therapy and does not result in overt Li toxicity. Since the observed changes in water consumption, urine output, urine osmolality, and blood Li levels were not significantly different between day 14 and day 21, the following experiments focused on effects of the Li-added diet for 14 days.

Fig. 1. Polydipsia and polyuria associated with lithium (Li) feeding. Groups of Sprague-Dawley rats (n = 5/group) were fed control or Li-added diet for 21 days. Water intake and urine output were monitored periodically. Body weight (A), water intake (B), urine output (C), and urine osmolality (D) in the 2 groups on days 0, 14, and 21 are shown. Results are means ± SE (n = 5). *Significantly different from corresponding value in control diet group. Mean values of urine output and urine osmolality in Li-fed rats on day 14 and day 21 are not significantly different from each other.

Fig. 2. Decreased protein abundance of aquaporin (AQP)2 associated with Li feeding. Groups of Sprague-Dawley rats (n = 4/group) were fed control or Li-added diet for 21 days and then euthanized. Inner medullas were processed for the determination of AQP2 protein abundance by Western blotting. A: AQP2 protein bands as visualized by Western blotting. B: densitometry values of 29-kDa and 35- to 50-kDa protein bands of AQP2 water channel seen in A. The sharp 29-kDa band corresponds to the native AQP2 protein molecule, whereas the smear from 35 kDa to 50 kDa represents the various glycosylated forms of AQP2 molecule. Results are means ± SE (n = 4). *Significantly different from corresponding value in control diet group.
induced NDI. In preliminary experiments we examined the adenosine 5'-O-(3-thiotriphosphate) (ATPγS)-stimulated release of PGE2 by freshly prepared fractions enriched in inner medullary collecting ducts from rats fed control or Li-added diets for 14 or 21 days. We observed that at both time points ATPγS, the universal P2y receptor agonist, caused enhanced PGE2 release by inner medullary collecting ducts of Li-fed rats compared with control diet-fed rats. Furthermore, at both time points, the magnitude of the purinergic-driven enhanced release of PGE2 in Li-fed rats was comparable (data not shown). Hence in the following experiments we studied the effect of feeding the Li-added diet for 14 days only. In addition, we used other P2y receptor agonists, namely UTP and ADP, to understand the nature of the P2y receptor subtype involved. In these experiments, medullary collecting ducts from control diet-fed rats released significantly higher amounts of PGE2 into the incubation medium when stimulated with 50 μM ATPγS or UTP, but not ADP (Fig. 4A). On the other hand, medullary collecting ducts from Li-fed rats released significant amounts of PGE2 into the incubation medium when stimulated by ATPγS, UTP, and ADP (Fig. 4A) compared with the vehicle group. Furthermore, the absolute amounts of PGE2 released by these three nucleotides in Li-fed rats were comparable (Fig. 4A) and were not significantly different from one another. In addition, the amounts of PGE2 released by the medullary collecting ducts of Li-fed rats, both under basal conditions (vehicle) and in response to the three nucleotides, were significantly higher compared with the corresponding releases in the control rats (Fig. 4B). Thus these findings suggest that enhanced purinergic-driven PGE2 release by inner medullary collecting ducts may be an early phenomenon in Li-induced NDI, which runs in parallel to the development of polydipsia, polyuria, and rise in blood Li levels. In addition, since ADP also elicited enhanced PGE2 release by inner medullary collecting ducts of Li-fed rats, it is possible that P2y receptor subtype(s) other than P2y2 may also be a key player in Li-induced NDI.

**Urinary excretion of PGE2 metabolite.** PGE2 in the urine is not stable. Hence we converted it to a stable metabolite and assayed the metabolite content of the urine samples. Figure 3 shows that the PGE2 metabolite content in Li-fed rats is about twofold higher compared with rats fed the control diet. This is seen for both nanograms per milligram of urinary creatinine and nanograms per 24 h. These data, which support the earlier findings by other investigators (42), indicate that in our model of Li-induced NDI there is also increased production of renal prostaglandins.

**Nucleotide-stimulated release of PGE2 by inner medullary collecting duct.** To validate our hypothesis that purinergic signaling may play a key role in the pathogenesis of Li-induced NDI, we examined whether nucleotide-stimulated PGE2 release by inner medullary collecting ducts is enhanced in Li-induced NDI. In preliminary experiments we examined the adenosine 5'-O-(3-thiotriphosphate) (ATPγS)-stimulated release of PGE2 by freshly prepared fractions enriched in inner medullary collecting ducts from rats fed control or Li-added diets for 14 or 21 days. We observed that at both time points ATPγS, the universal P2y receptor agonist, caused enhanced PGE2 release by inner medullary collecting ducts of Li-fed rats compared with control diet-fed rats. Furthermore, at both time points, the magnitude of the purinergic-driven enhanced release of PGE2 in Li-fed rats was comparable (data not shown). Hence in the following experiments we studied the effect of feeding the Li-added diet for 14 days only. In addition, we used other P2y receptor agonists, namely UTP and ADP, to understand the nature of the P2y receptor subtype involved. In these experiments, medullary collecting ducts from control diet-fed rats released significantly higher amounts of PGE2 into the incubation medium when stimulated with 50 μM ATPγS or UTP, but not ADP (Fig. 4A). On the other hand, medullary collecting ducts from Li-fed rats released significant amounts of PGE2 into the incubation medium when stimulated by ATPγS, UTP, and ADP (Fig. 4A) compared with the vehicle group. Furthermore, the absolute amounts of PGE2 released by these three nucleotides in Li-fed rats were comparable (Fig. 4A) and were not significantly different from one another. In addition, the amounts of PGE2 released by the medullary collecting ducts of Li-fed rats, both under basal conditions (vehicle) and in response to the three nucleotides, were significantly higher compared with the corresponding releases in the control rats (Fig. 4B). Thus these findings suggest that enhanced purinergic-driven PGE2 release by inner medullary collecting ducts may be an early phenomenon in Li-induced NDI, which runs in parallel to the development of polydipsia, polyuria, and rise in blood Li levels. In addition, since ADP also elicited enhanced PGE2 release by inner medullary collecting ducts of Li-fed rats, it is possible that P2y receptor subtype(s) other than P2y2 may also be a key player in Li-induced NDI.

**Fig. 3.** Urinary excretion of prostaglandin (PG)E2 metabolite in rats fed control or Li-added diet for 14 days. Twenty-four-hour urine samples were collected from rats fed control or Li-added diet (n = 8/group) and processed for the assay of PGE2 metabolite. A: urinary PGE2 metabolite expressed as nanograms per milligram of creatinine. B: urinary excretion of PGE2 metabolite expressed as nanograms per 24 h. Results are means ± SE of triplicate incubations for each condition. *P < 0.01, **P < 0.001.

**Fig. 4.** Nucleotide-stimulated PGE2 release by inner medullary collecting duct preparations from rats fed control or Li-added diet for 14 days. Fractions enriched in medullary collecting duct were freshly prepared by pooling inner medullas (n = 5 rats/group). Aliquots of fractions were warmed up to 37°C before challenging with each nucleotide at 50 μM for 20 min. Reactions were stopped by adding chilled buffer. PGE2 released into the medium was assayed and normalized to the protein contents of the respective incubations. Results are means ± SE of triplicate incubations for each condition. A: absolute amounts of PGE2 released as nanograms per milligram of protein under each condition. B: PGE2 released by the medullary collecting ducts of Li-fed rats as % over corresponding PGE2 release by control diet-fed rats. Statistical analysis by ANOVA: A, control diet group: *mean values in adenosine 5'-O-(3-thiotriphosphate) (ATPγS) and UTP incubations significantly different from mean value in corresponding vehicle incubations (P < 0.01). A, Li diet group: *mean values in ATPγS, ADP, and UTP incubations significantly different from mean values in corresponding vehicle incubations (P < 0.01). B: *P < 0.01, **P < 0.001.
Expression of P<sub>2y</sub> receptor subtypes in the inner medulla. The qualitative and quantitative differences observed between the inner medullary collecting ducts from control and Li diet-fed rats after nucleotide-induced PGE<sub>2</sub> release suggested the involvement of more than one subtype of P<sub>2y</sub> receptor in Li-fed rats (Table 2). Hence we examined the potential changes in receptor expression by real-time RT-PCR with RNA extracted from the inner medullas. We choose to determine the relative expression of P<sub>2y1</sub>, P<sub>2y2</sub>, P<sub>2y4</sub>, and P<sub>2y6</sub> receptors, because these four receptors are coupled to the phosphoinositol signaling pathway and thus are relevant for this study on NDI (Table 2). The results show that in rats fed control diet P<sub>2y2</sub> is the predominant P<sub>2y</sub> receptor subtype expressed in the inner medulla, followed by P<sub>2y6</sub>. However, after Li diet for 14 days, P<sub>2y2</sub> receptor expression was decreased to ~57%, associated with a 3.4-fold (340%) increase in the expression of P<sub>2y4</sub> receptor relative to the rats on control diet. Thus these data suggest that both P<sub>2y2</sub> and P<sub>2y4</sub> receptors may be involved in the enhanced production of PGE<sub>2</sub> by inner medullary collecting ducts. Together, these data indicate that purinergic signaling may play a previously unidentified potential role in the genesis of polyuria of Li-induced NDI by driving the increased production of PGE<sub>2</sub> by medullary collecting ducts.

**DISCUSSION**

Although increased production of renal PGE<sub>2</sub> has been implicated in the polyuria of Li-induced NDI, the driving force for this is not known. Using a classical model of Li-induced NDI, we documented 1) markedly enhanced nucleotide-driven PGE<sub>2</sub> release by the medullary collecting duct; 2) potential involvement of P<sub>2y2</sub> and/or P<sub>2y4</sub> receptors in the enhanced PGE<sub>2</sub> release by medullary collecting duct; 3) marked increase in the expression of P<sub>2y4</sub> receptor mRNA in the inner medulla; and 4) predominant localization of P<sub>2y2</sub> and P<sub>2y4</sub> receptor proteins in the medullary collecting duct. Together, these data suggest that purinergic signaling may play a previously unidentified potential role in the genesis of polyuria of Li-induced NDI.
overarching role in balancing the effect of AVP on the urinary concentration mechanism.

Previously we demonstrated (54) that inner medullary collecting ducts of normal rats, when stimulated by ATP/UTP, produce and release PGE2, which is consistent with the presence of P2y2 receptor. Interestingly, however, in the present study when rats were fed Li-added diet for 14 days, the nucleotide-stimulated PGE2 release revealed both qualitative and quantitative differences compared with the PGE2 release by medullary collecting duct of control diet-fed rats. Qualitatively, the medullary collecting duct from Li-fed rats responded to ADP, in addition to ATP/UTP (Fig. 4B), suggesting the potential involvement of P2y6 and/or P2y1 receptor subtypes as well, in addition to P2y2 receptor (Table 2).

Fig. 6. Confocal immunofluorescence localization of P2y2 and P2y4 receptor proteins in the inner medullas of rats fed control or Li-added diets for 14 days. Kidney sections were processed for immunofluorescence microscopy with specific rabbit polyclonal antibodies to P2y2 or P2y4 receptors in conjunction with Cy5-conjugated donkey rabbit IgG. Cy5 was detected with a red HeNe laser at 633 nm. A and C: representative profiles for P2y2 receptor in control and Li diet-fed rats, respectively. B and D: representative profiles for P2y4 receptor in control and Li diet-fed rats, respectively. Sections used for generating A and B were obtained from the same block of paraffin-embedded kidney from a rat fed control diet. Similarly, sections used for generating C and D were obtained from the same block of paraffin-embedded kidney from a rat fed Li-added diet. Arrows indicate red fluorescence of Cy5 in medullary collecting duct. Images only depict localization of P2y2 and P2y4 receptor proteins in the inner medullary structures, and the intensity of the fluorescence does not correspond to the levels of their protein abundance.

Fig. 7. The cascade of events in the biosynthesis of PGE2 and the potential utility of purinergic antagonists to block the increased production of PGE2 in Li-induced nephrogenic diabetes insipidus. The availability of free arachidonic acid is often the rate-limiting step in the synthesis of PGE2 by cyclooxygenases (COX-1 or COX-2). The release of arachidonic acid from membrane phospholipids is critically dependent on the activity of phospholipases. The activation of phospholipases is in turn dependent on signal transduction through G protein-coupled receptors that act through phosphoinositide signaling pathway, such as the P2y purinergic receptors. Hence, blocking the activity of P2y receptors by the use of specific receptor antagonists should effectively decrease the release of free arachidonic acid for the synthesis of PGE2 by COX-1 or COX-2, and thus ameliorate Li-induced polyuria.
Quantitatively, the amounts of PGE_2 released by the medullary collecting duct of Li-fed rats in response to the three nucleotides tested were significantly higher than the corresponding amounts in control diet-fed rats (Fig. 4B). Together these two findings indicate that Li feeding sensitizes the purinergic signaling in the medullary collecting ducts to extracellular nucleotides. In light of these ex vivo data generated by the use of freshly prepared fractions enriched in inner medullary collecting ducts, it is reasonable to deduce that the twofold increase in urinary PGE_2 metabolite seen in Li-induced NDI may be due to increased production of PGE_2 by medullary collecting ducts in vivo.

The observed qualitative shift in the purinergic signaling in medullary collecting duct following Li feeding is associated with a marked 3.4-fold increase in the mRNA expression of P_2y4 receptor, suggesting the potential involvement of this receptor in Li-induced NDI (Fig. 5B). However, the mRNA expression of P_2y6 receptor, the other potential candidate based on nucleotide-stimulated release of PGE_2, was not changed by Li feeding. Despite the observed significant decrease in expression, P_2y2 receptor still remained the predominant P_2y receptor (Fig. 5A). Furthermore, preliminary data we obtained showed that genetic deletion of P_2y2 receptor in mice results in marked resistance (~50%) to Li-induced polyuria, indicating the potential involvement of P_2y2 receptor in the genesis of NDI. In addition, it is well known that the activity of G protein-coupled receptors, such as the P_2y, receptors, is regulated by a variety of receptor-associated factors independent of receptor expression itself (10, 13, 20). Hence at this stage we cannot rule out the lack of involvement of P_2y2 receptor in Li-induced NDI based on its mRNA expression alone.

After documenting the potential involvement of P_2y4 receptor by functional analysis and mRNA expression, we then turned to examine the expression and localization of P_2y4 receptor protein in the inner medulla by confocal laser immunofluorescence microscopy and compared them with the expression and localization of P_2y2 receptor. We observed that, similar to P_2y2 receptor, P_2y4 receptor protein is expressed in the medullary collecting duct. However, the subcellular distribution of these two proteins apparently differed in control versus Li-fed rats. Pending more detailed studies, in the present work we did not pursue these aspects further.

Less is known about the role of P_2y4 receptor in the collecting duct biology compared with advances in P_2y2 receptor biology. Recently Wildman and associates (55), using an approach of whole cell patch clamp of principal cells of split-open collecting ducts from sodium-restricted rats, found that activation of P_2y2 and/or P_2y4 receptors inhibited the activity of epithelial sodium channel (ENaC). In parallel, they found that P_2y4 mRNA levels were insignificant in the microdissected sodium-repleted rats, whereas there was a marked abundance of P_2y4 receptor mRNA in sodium-restricted rats (55). Hence it is possible that, at least under pathophysiological conditions, the P_2y2 and P_2y4 receptors may function synergistically.

Increased expression of cyclooxygenases (COX-1 and COX-2) in Li-induced NDI has been implicated in the increased production of PGE_2 (30, 42). However, the availability of free arachidonic acid, the substrate, itself is considered by many investigators as the initial and often the rate-limiting step in the production of PGE_2 (4, 22, 37). In this context, our study demonstrates that enhanced purinergic signaling in the medullary collecting duct following Li feeding may hold the key for the increased production of free arachidonic acid from membrane phospholipids via phospholipases as depicted in Fig. 7. The increased expression of COX enzymes in Li-induced NDI may only partially facilitate the rapid formation of PGE_2 from the increased availability of free arachidonic acid due to enhanced purinergic signaling.

Finally, the long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs), such as indomethacin, and COX-2-specific inhibitors (celecoxib or rofecoxib), which suppress PGE_2 production by directly inhibiting cyclooxygenases, is known to cause permanent renal toxicity and damage and/or elevated serum Li to toxic levels (6, 16, 39, 41). Hence replacement of the current side effect-prone drugs with new drugs based on improved understanding of the molecular pathophysiology of Li-induced NDI should result in improved efficacy and fewer side effects in the clinic. This work represents the first step in that direction. The potential role of purinergic signaling in the enhanced production and release of PGE_2 by the medullary collecting duct in Li-induced NDI uncovered by us opens the possibility of targeting purinergic signaling by specific receptor antagonists to decrease the PGE_2 production in Li-induced NDI as depicted in Fig. 7.
