Gubhaju L, Sutherland MR, Yoder BA, Zulli A, Bertram JF, Black MJ. Is nephrogenesis affected by preterm birth? Studies in a non-human primate model. Am J Physiol Renal Physiol 297: F1668–F1677, 2009. First published September 16, 2009; doi:10.1152/ajprenal.00163.2009—Nephrogenesis occurs predominantly in late gestation at a time when preterm infants are already delivered. The aims of this study were to assess the effect of preterm birth and the effect of antenatal glucocorticoid treatment on nephrogenesis. Preterm baboons, which were delivered at 125 days gestation and ventilated for up to 21 days postnatally, were compared with gestational controls. A cohort of preterm baboons that had been exposed to antenatal glucocorticoids were compared with unexposed preterm baboons. The number of glomerular generations was estimated using a medullary ray glomerular-counting method, and glomerular number was estimated using unbiased stereology. CD31 and WT-1 localization was examined using immunohistochemistry and VEGF was localized using in situ hybridization. The number of glomerular generations was not affected by preterm birth, and total glomerular numbers were within the normal range. Kidneys were significantly enlarged in preterm baboons with a significant decrease in glomerular density (number of glomeruli per gram of kidney) in the preterm kidney compared with gestational controls. Neonates exposed to antenatal steroids had an increased kidney-to-body weight ratio and also more developed glomeruli compared with unexposed controls. Abnormal glomeruli, with a cystic Bowman’s space and shrunken glomerular tuft, were often present in the superficial renal cortex of both the steroid-exposed and unexposed preterm kidneys; steroid exposure had no significant effect on the proportion of abnormal glomeruli. The proportion of abnormal glomeruli in the preterm kidneys ranged from 0.2 to 18%. In conclusion, although nephrogenesis is ongoing in the extrauterine environment, our findings demonstrate that preterm birth, independent of steroid exposure, is associated with a high proportion of abnormal glomeruli in some, but not all neonatal kidneys. Whether final nephron endowment is affected in those kidneys exhibiting a high proportion of abnormal glomeruli is yet to be confirmed.

baboon; kidney; glomerulogenesis

The incidence of preterm birth is currently high, with 13% of all babies born preterm in the United States (17) and 8% in Australia (25). In addition, the survival of preterm infants, including extremely preterm infants, has improved substantially over recent years such that infants born as early as 26 wk of gestation now have a 60–80% chance of survival (28, 34). In the human kidney, nephrogenesis commences at around week 5 of gestation and is complete by 36 wk of gestation (32).

After this point, no more new nephrons are formed for the life of the individual. Nephrogenesis predominantly occurs in late gestation at a time when preterm infants are already delivered (20). It is important to gain an understanding of the effects of preterm birth on nephrogenesis since there is accumulating epidemiological data linking prematurity birth with an increased incidence of hypertension (8, 22) and adverse renal function (23) later in life; this may be linked to a reduced nephron endowment after birth (4).

To our knowledge, there has only been one previously published study which has investigated the effects of preterm birth on nephrogenesis. In the autopsy study, conducted by Rodriguez et al. (31), a reduced number of glomerular generations, potentially indicative of a nephron deficit, were reported in kidneys of infants that were born preterm. It is important to note, however, that the cohort of preterm infants in the human autopsy study included a number of infants that were not only preterm but also intrauterine growth restricted (IUGR). Since it is well known that IUGR adversely impacts nephrogenesis (19, 40), it is difficult to clearly differentiate the effects of preterm birth and IUGR on nephrogenesis in the previous study. In addition, any abnormal effects observed in the human autopsied kidneys may have been a direct result of a failure of the baby to thrive after birth rather than preterm birth per se. Hence in this study we have examined the effects of preterm birth, in the absence of IUGR, in a non-human primate model where the neonates were in relatively good health after birth.

The improved survival of preterm neonates, such as those born as early as 27 wk of gestation, can be largely attributed to the use of antenatal glucocorticoids. These have been shown to accelerate lung maturation, thus reducing neonatal morbidity and mortality (11). Previous experimental studies have demonstrated a link between glucocorticoid exposure early in utero and a reduction in nephron endowment (5, 30, 38). There is no evidence to date, however, as to the effects of clinical doses of antenatal glucocorticoids on nephrogenesis.

Hence, the aims of the current study were first to assess the effects of preterm birth on nephrogenesis, and second to determine the effects of prenatal glucocorticoid treatment on nephrogenesis. To address these aims, we have used a baboon (non-human primate) model, where the ontogeny of the kidney closely resembles that of the human (18) and the preterm neonates are cared for in a neonatal intensive care unit after birth in a similar manner as human infants (6). In our model, the baboons are delivered at 125 days gestation (0.67 of total length of gestation), a time point at which nephrogenesis is still ongoing in the baboon (18) and is approximately equivalent to 27 wk of gestation in the human (27).
METHODS

Induction of Preterm Delivery and Postnatal Care

All animal experiments were undertaken at the Southwest Foundation for Biomedical Research (San Antonio, TX). All animal-handling procedures were approved to conform to the American Association for Accreditation of Laboratory Animal Care guidelines. Fetal baboons were delivered prematurely by cesarean section at 125 days gestation (term = 185 days). After birth, all preterm neonates were intubated, administered 100 mg/kg surfactant (Survanta; donated by Ross Products, Columbus, OH), and ventilated with pressure-limited infant ventilators (InfantStar; donated by Infrasonics, San Diego, CA). All preterm neonates were also treated with ampicillin and gentamycin for the first 7–10 days of life. Further doses of antibiotics were only administered in cases of clinically suspected infection; two preterm animals were administered additional doses of vancomycin and a cephalosporin antibiotic, Fortaz (days 10–13 of life in one preterm neonate and days 10–17 of life in the other preterm neonate). A detailed description of the postnatal clinical and nutritional management of the preterm baboons has been previously published (39). Briefly, during the first 24 h of life, all animals received heparinized normal saline and 5% dextrose/water and supplemental calcium infusion. Sufficient fluids were administered to maintain electrolyte homeostasis, a minimal urine output of 1–2 ml/kg·h·1, and blood pressure within the normal range. Parenteral nutrition was initiated at 24 h of life with amino acids, electrolytes, vitamins, and trace elements. If clinically stable, enteral nutrition was initiated on day 7 of life; 10 ml·kg⁻¹·day⁻¹ of donated human breast milk was administered by intermittent gastric infusion and once 100 ml·kg⁻¹·day⁻¹ was tolerated, feeds were changed to Primilac (Bio-Serv, Frenchtown, NJ). Serum electrolytes, glucose, and hematocrit were maintained within the normal range for the extremely low birth-weight infant. Developed glomeruli were not counted.

Kidneys were immersion-fixed at necropsy, cut into halves, sliced into 2-mm slices, and sampled using a smooth fractionator approach (29). The sampled slices (8–15 slices/kidney) were embedded in glycolmethacrylate to be used for the estimation of the number of glomeruli, the number of glomerular generations, kidney volume, mean renal corpuscle volume, and the proportion of abnormal glomeruli. Complete slices containing both cortex and medulla were randomly selected from the remaining slices, embedded in paraffin, and sectioned at 5 μm for the immunohistochemical analyses.

Tissue Processing, Embedding, and Sectioning

Kidneys were immersion-fixed at necropsy, cut into halves, sliced into 2-mm slices, and sampled using a smooth fractionator approach (29). The sampled slices (8–15 slices/kidney) were embedded in glycolmethacrylate to be used for the estimation of the number of glomeruli, the number of glomerular generations, kidney volume, mean renal corpuscle volume, and the proportion of abnormal glomeruli. Complete slices containing both cortex and medulla were randomly selected from the remaining slices, embedded in paraffin, and sectioned at 5 μm for the immunohistochemical analyses.

Qualitative and Quantitative Assessment of Nephrogenesis

Morphological assessment of nephrogenesis. The presence of undifferentiated metanephric mesenchyme, the branching ureteric bud, and developing glomerular structures in the form of comma- and S-shaped bodies in the outer cortex indicated that nephrogenesis was ongoing. Developed glomeruli exhibited a well-defined glomerular tuft surrounded by a distinct Bowman’s space and capsule.

Measurement of nephrogenic zone thickness. The width of the nephrogenic zone was measured using image-analysis software (Image Pro Plus v. 6.0 for Windows, Media Cybernetics; Silver Spring, MD). This method was based on a previous method used to measure nephrogenic zone thickness to assess renal maturity in human neonatal kidneys (9, 12). From the serially sectioned glycolmethacrylate sections, one complete intact section from each sampled kidney slice (8–15 complete sections/kidney) was used to estimate the width of the nephrogenic zone. Each section was viewed at ×200 magnification, and the width of the nephrogenic zone was measured in three separate regions of each kidney section. The nephrogenic zone was defined as the area in the outer renal cortex exhibiting developing glomerular structures in the form of comma and S-shaped bodies. An average nephrogenic zone width was determined for each kidney.

Estimation of glomerular generation number. One complete intact section from each glycolmethacrylate block (8–15 blocks/kidney) was examined. In each sampled section, five clearly distinguishable medullary rays from separate regions were identified. The number of developed glomeruli (inclusive of normal and abnormal glomeruli) along one side of each medullary ray were counted, and an average number for each kidney was then determined (36).

Estimation of the number of developed glomeruli, kidney volume, and mean renal corpuscle volume. Glycolmethacrylate blocks (8–15/ kidney) were serially sectioned at 20 μm with every tenth and eleventh sections collected and stained with hematoxylin and eosin. Kidney volume was then estimated using the Cavalieri principle (29). One pair of complete intact sections from each block was used for the estimation of glomerular number. Using an unbiased physical dissector/fractionator technique, renal corpuscle volume and the number of glomeruli (and thereby nephrons) in the kidneys were stereologically estimated (3, 18). In the counting of glomeruli, only developed glomeruli (inclusive of normal and abnormal glomeruli) exhibiting a well-defined Bowman’s space and capsule were included; developing glomerular structures such as comma-shaped and S-shaped bodies were not counted.
Characterization of Abnormal Glomeruli

Quantitative assessment of abnormal glomeruli. While the stereological estimation of glomerular number was being undertaken, in each field of view the number of normal and abnormal glomeruli (exhibiting a shrunken glomerular tuft and dilated Bowman’s space) was recorded and the percentage of abnormal glomeruli within the whole kidney was determined.

Immunohistochemical analysis with the endothelial cell marker CD31 and podocyte marker Wilms tumor suppressor gene-1. Five-micrometer paraffin sections were deparaffinized, rehydrated, and rinsed in water and 10 mM Tris hydrochloride. For Wilms tumor suppressor gene-1 (WT-1) staining, heat-induced antigen retrieval (3 × 5 min in a microwave) was undertaken in Tris-EDTA buffer (10 mM Tris Base, 1 mM EDTA, 0.05% Tween 20, pH 9.0). Endogenous peroxidase activity was blocked by placing slides in an endogenous enzyme block solution (Dako) for 15 min. Sections were then incubated with 1% goat serum for 20–30 min. Subsequently, sections were incubated with the primary antibody, either a mouse anti-human CD31 monoclonal antibody (1:15 dilution, JC70A, Dako) or a mouse anti-human WT-1 monoclonal antibody (1:100 dilution, M3561, Dako) overnight. The negative control consisted of a mouse IgG antibody raised against bacterial glucose oxidase (Dako). The sections were then incubated with 1% horse serum for 2 h with the Envision molecule (Dako), and 3’3’-diaminobenzidine tetrachloride was used to detect antibody binding. All sections were counterstained with hematoxylin.

In situ hybridization of VEGF mRNA. For the synthesis of riboprobes, a cDNA fragment of human VEGF121 (gift of Steven Stacker, Ludwig Institute, Melbourne, Australia) was cloned into a BSKS vector (Stratagene, La Jolla, CA) and linearized with HindIII. An anti-sense riboprobe was generated from the template incorporating DIG-UTP (Roche Applied Science, Mannheim, Germany) into run-off transcripts using T7 RNA polymerase. A sense riboprobe was also generated. In situ hybridization was undertaken in 4-μm paraffin sections as described by Sutherland et al. (36).

Statistical Analysis

Statistical analyses were performed using GraphPad Prism Version 4.0 for Windows (GraphPad Software, San Diego, CA). A one-way analysis of variance was utilized to compare data between the 125- and 146-day gestational control groups and the preterm +21 day group. This was followed by a Tukey’s post hoc analysis.

Data between steroid-exposed and unexposed neonates were analyzed using a Student’s t-test. To compare data between steroid-exposed and unexposed neonates from different postconceptional time points, a two-way analysis of variance was utilized. Physiological data were analyzed using a repeated measures two-way analysis of variance followed by Bonferroni’s post hoc analysis.

Linear regression analyses were performed to determine whether there were significant correlations between glomerular number and postconceptional age, birth weight, kidney weight, kidney volume, and renal corpuscle volume. Included in these analyses were data from steroid-exposed and unexposed animals from 0 to +6 days and preterm +14 days groups. An analysis of covariance was used to determine any differences in the linear regressions between the preterm group and the gestational controls. Statistical significance was accepted as P < 0.05.

RESULTS

Effect of Preterm Birth on Nephrogenesis in the Context of Antenatal Steroids

Postnatal fetal physiology. Arterial blood gases (pH, PaCO₂, PaO₂), fluid intake, urine output, and mean arterial blood pressure of preterm neonates from birth until postnatal day 21 were all within the accepted clinical range.

Body weights, kidney weights, and kidney volumes. All fetal baboons had birth weights above the 10% reference
range for premature baboons delivered at this gestational
time point. There was no significant difference in birth
weights between the 125-day gestational control group and
the preterm + 21 days group (Table 1). Necropsy weights of
the preterm + 21 days group were significantly less ($P =
0.002$) compared with the 146-day gestational age-matched
controls. Although all preterm baboons lost weight after
birth, relative kidney weights and volumes were significantly increased compared with the 125- and 146-day ges-
tentional controls.

IS NEPHROGENESIS AFFECTED BY PRETERM BIRTH?

AJP-Renal Physiol • VOL 297 • DECEMBER 2009 • www.ajprenal.org

by 10.220.32.246 on April 13, 2017 http://ajprenal.physiology.org/ Downloaded from
There was no significant difference in the mean renal corpuscle volume between the preterm+21 days groups and the 146-day gestational age-matched control group (Table 1). There was no significant correlation between renal corpuscle volume and glomerular number.

Effect of Prenatal Maternal Glucocorticoids on Nephrogenesis

Postnatal fetal physiology. Exposure to antenatal maternal glucocorticoids at 123 and 124 days gestation did not significantly affect arterial blood-gas levels (pH, \( Pa_{CO_2} \), \( Pa_{O_2} \)) following preterm delivery at 125 days gestation (Table 2). There was no significant difference in fluid intake or urine output between the two groups (Fig. 3, A and B). At 72 h of life, however, mean arterial blood pressure was significantly elevated in the steroid-exposed group (\( P < 0.05 \)) (Fig. 3C). There was no significant difference in mean arterial blood pressure between the two groups at postnatal day 21.

Body weights, kidney weights, and kidney volumes. Antenatal exposure to steroids (123 and 124 days gestation) did not affect fetal birth weight at 125 days gestation, necropsy weight at postnatal day 21, or absolute kidney weights or kidney volumes (Table 3). Kidney weight-to-body weight ratio, however, was significantly greater in the animals exposed to antenatal steroids (\( P = 0.02 \)).

Assessment of nephrogenesis. There were no apparent morphological differences in kidney structure between the steroid-exposed and unexposed preterm groups at postnatal day 21. Kidneys from both the preterm+21 days group and the preterm+21 days+steroids group exhibited a clearly visible nephrogenic zone, and there was no significant difference in the width of the nephrogenic zones (94.2 ± 6.5 vs. 100.5 ± 10.6 μm, respectively).

There was no difference in the number of glomerular generations formed within the kidney between the steroid-exposed and unexposed groups (Table 3).

There was a significant increase in renal corpuscle volume in relation to maternal steroid treatment was different in kidneys at 125 days gestation compared with preterm kidneys at postnatal day 21 (Table 3). At 125 days gestation, there was a significant increase in renal corpuscle volume whereas on postnatal day 21 there was a significant decrease.

---

Assessment of nephrogenesis. In the preterm kidneys at postnatal day 6, 14, and 21 and in the 125- and 146-day gestational controls, there was morphological evidence of ongoing nephrogenesis (Fig. 1A). In the preterm kidneys at postnatal day 21, nephrogenic zone thickness was significantly less compared with the 125-day gestational control group but not significantly different from the 146-day gestational control group (Fig. 1B).

The number of glomerular generations increased significantly from 125 days gestation to 175/185 days gestation (Fig. 1). The number of glomerular generations in the preterm+21 days group was not significantly different from the number of generations in the 146-day gestational age-matched controls, and was significantly higher than the 125-day group.

In accordance with the glomerular generation data, the number of developed glomeruli in the preterm+21 days group was significantly greater compared with the 125-day gestational controls, but was not significantly different from the 146-day gestational age-matched controls (Table 1).

Statistically significant correlations were found between glomerular number and postconceptional age (\( r^2 = 0.781, P = 0.0001 \)) and between glomerular generations and postconceptional age (\( r^2 = 0.613, P = 0.003 \)) when all preterm animals were combined (Fig. 1, D and E). In the two kidneys from the preterm+6 days group, there were 184,234 and 202,316 developed glomeruli and in the kidneys from postnatal day 14 (\( n = 2 \)) there were 140,185 and 178,661 developed glomeruli.

Birth weight correlated significantly with glomerular number in both the preterm neonates (\( r^2 = 0.438, P = 0.02 \)) and the gestational controls (\( r^2 = 0.680, P = 0.01 \)). In the preterm neonates, there was no significant correlation between necropsy weight and glomerular number.

Importantly, there was a very strong correlation between kidney weight and glomerular number in both the preterm neonates (\( r^2 = 0.703, P = 0.0007 \)) and gestational controls (\( r^2 = 0.664, P = 0.01 \)); however, there was a significant difference in the slopes of the regression lines (\( P = 0.048 \)) such that in the preterm kidneys there were 83,840 glomeruli/g compared with 193,400 glomeruli/g in the gestational controls (Fig. 2).
Characterization of Abnormal Glomeruli

We observed in many of the preterm kidneys (both steroid exposed and unexposed), at all postnatal time points, the presence of abnormal glomeruli; these were grossly enlarged and exhibited a cystic Bowman’s space and shrunken glomerular tuft. The abnormal glomeruli were only located in the preterm +21 days-steroids group (n = 4) compared with the preterm +21 days-steroids group (n = 4). Steroid-exposed neonates (∗∗), unexposed controls. Data were analyzed using a repeated-measures 2-way analysis of variance followed by Bonferroni’s post hoc analysis. At 72 h of life, mean arterial blood pressure was significantly higher in the steroid-exposed animals compared with unexposed controls (P < 0.001).

Values are means ± SE with data range in parentheses. Neonates at each time point were exposed to maternal betamethasone treatment at 123 and 124 days gestation (+steroids; data as shown in Table 2) or were unexposed (−steroids). Data were analyzed using a 2-way analysis of variance.
outer renal cortex and exhibited an immature morphology; the clearly recognizable glomerular anlage was surrounded by a cup-shaped layer of epithelial cells.

Quantitative assessment of abnormal glomeruli. There was wide variation in the proportion of abnormal glomeruli within the preterm kidneys (Tables 4 and 5); steroid exposure did not affect the proportion of abnormal glomeruli in the kidney. The proportion of abnormal glomeruli in the preterm kidneys ranged from 0.2 to 18.3%. Of the 12 preterm kidneys analyzed (inclusive of steroid exposed and unexposed), 50% had more than 4% of their glomeruli appearing abnormal. In three preterm kidneys, the proportion of abnormal glomeruli was >10%. In one of the preterm baboons, the morphology of the kidney was grossly abnormal, with 18% of the glomeruli abnormal. The proportion of abnormal glomeruli in the kidneys of the gestational controls was considered negligible (Table 4).

Immunohistochemical localization of endothelial cell marker CD31. In kidney sections at 146 days gestation, the well-developed glomeruli adjacent to the nephrogenic zone demonstrated profuse positive staining for CD31 (Fig. 4A). In the preterm kidneys, the abnormal glomeruli exhibited little CD31 immunostaining compared with well-developed glomeruli observed in the same section.

Immunohistochemical localization of podocyte marker WT-1. Profuse WT-1 staining was observed in the glomerular tuft of well-developed, normal glomeruli from preterm kidneys (Fig. 4B). In the abnormal glomeruli from the preterm kidneys, however, WT-1-positive immunostaining was localized to the layer of epithelial cells surrounding the spherical mass of cells of the glomerular tuft. Positive immunostaining was also localized to the epithelial cells of Bowman’s capsule in the abnormal glomeruli.

In situ localization of VEGF mRNA. VEGF mRNA was localized to the glomerular podocytes in both the preterm kidneys and gestational controls including the abnormal glomeruli (Fig. 4C).

DISCUSSION

The findings of this study clearly demonstrate that nephrogenesis continues after preterm birth in the steroid-exposed and unexposed primate kidney. There was an increase in the number of glomerular generations and total glomeruli in the extrauterine environment, with no differences found between the preterm kidneys and their gestational age-matched controls, in the context of antenatal steroids. Interestingly, exposure to antenatal glucocorticoids before preterm birth led to renal hypertrophy and an increase in the number of developed glomeruli in the kidney compared with unexposed kidneys. Many of the glomeruli located in the outer renal cortex of the preterm kidney, in both the steroid-exposed and unexposed baboon neonates, often appeared abnormal. Immunohistochemical analyses of these abnormal glomeruli showed that they were in a relatively immature state of development, poorly vascularized, and are therefore likely to be nonfunctional.

Although all preterm baboons lost weight after birth, there appeared to be substantial postnatal kidney growth, with the relative kidney weights and kidney volumes significantly higher in the preterm animals compared with the gestational controls. Similar findings have been previously reported in preterm babies (21). The renal hypertrophy observed in the preterm kidneys did not appear to be attributed to differences in the thickness of the nephrogenic zone or in the size of glomeruli, thus implying tubular hypertrophy.

Our results demonstrate that nephrogenesis unequivocally occurs postnatally in both steroid-exposed and unexposed preterm neonates; morphologically, there was evidence of a nephrogenic zone and, when assessed quantitatively, the number of glomerular generations and the total number of developed glomeruli increased with postnatal age. The average number of developed glomeruli in the preterm kidneys (inclusive of steroid-exposed and unexposed preterm kidneys) was ~245,673, ranging from 138,078 to 304,186, which appears to be within the normal range for term baboon kidneys, albeit at the lower end (18). Total glomerular number is also expected to increase further since nephrogenesis, although nearing completion, was not finished by postnatal day 21.

In the context of antenatal steroids, there was no significant difference in the number of glomerular generations formed in the kidney between the preterm +21 days kidneys and their 146-day gestational age-matched controls. These findings are not consistent with those of Rodriguez et al. (31), who reported fewer glomerular generations within the kidneys of autopsied preterm infants. However, the discrepancy in findings is likely explained by a number of the preterm human neonates being intrauterine growth restricted in the study by Rodriguez et al., which is known to influence nephron endowment (19, 40).

We have previously reported a very strong correlation between renal size and glomerular number (18), and this association appears to be maintained after premature delivery since kidney weight significantly correlated with glomerular number in the preterm baboons. However, in the present study our linear regression analyses indicate that glomerular density (the number of glomeruli per gram of kidney) is substantially less in the preterm kidneys (Tables 4 and 5); steroid exposure did not affect the proportion of abnormal glomeruli within the preterm kidneys (18), and this association appears to be maintained after premature delivery since kidney weight significantly correlated with glomerular number in the preterm baboons. However, in the present study our linear regression analyses indicate that glomerular density (the number of glomeruli per gram of kidney) is substantially less in the preterm kidneys (83,840 glomeruli/g) compared with gestational controls (193,400 glomeruli/g); this is likely to be due to the relative increase in kidney size after preterm birth.

and not a change in the absolute number of glomeruli formed. Further studies would be necessary to investigate whether this difference in glomerular density reflects a change in renal tubular mass.

Our findings have demonstrated that antenatal exposure to glucocorticoids before preterm birth increases the number of developed glomeruli within the preterm baboon kidney. Certainly, this indicates that glucocorticoid administration has

Fig. 4. Representative photomicrographs of kidney sections from the 146-day gestational control group and the preterm + 21 days group immunostained with an endothelial cell marker (CD31; A), the Wilm’s tumor suppressor gene-1 (WT-1; B), and in situ hybridization for vascular endothelial growth factor (VEGF; C). The glomeruli from the 146-day gestational control group show profuse positive brown staining for CD31 (A). The abnormal glomeruli in the preterm + 21 days group are poorly vascularized, as shown by the scant positive brown staining for CD31 (A). WT-1-positive staining is localized to podocytes within the glomerular tuft of developed, normal glomeruli (B). In abnormal glomeruli, WT-1 staining is localized to podocytes surrounding the immature glomerular anlage (B). WT-1-positive immunostaining can also be observed in the parietal epithelial cells of Bowman’s capsule (arrows). VEGF-positive immunostaining (dark purple staining) was localized to the podocytes in the glomerular tuft (arrows, C). In an abnormal glomerulus from a preterm kidney, VEGF-positive podocytes stained dark purple were also observed (arrows, C).
accelerated glomerular maturation, which is in accordance with previous studies demonstrating that glucocorticoids induce organ maturation (13). Our findings also support the improvement in renal function demonstrated to occur in preterm infants exposed to steroids (1). Exposure to steroids also resulted in a greater increase in kidney weight-to-body weight ratio, suggesting that glucocorticoid treatment may be leading to renal hypertrophy. Previous studies in the preterm lamb, baboon, and human neonate have shown that glucocorticoid treatment increases mean arterial pressure, renal blood flow, and glomerular filtration rate, indicative of renal functional maturation, (1, 10, 35) which may be contributing to the renal hypertrophy observed in the current study. Indeed, mean arterial blood pressure was observed to be significantly elevated at 72 h of life in the preterm baboons exposed to antenatal steroids. Similar findings have also been reported in human infants, in which the effects of prenatal glucocorticoids appear to be limited to the early postnatal period (1, 37).

In accordance with previous studies (31, 36), abnormal glomeruli exhibiting a dilated Bowman’s space were observed in the outer renal cortex of both steroid-exposed and unexposed preterm kidneys, suggesting glomeruli formed in the extrauterine environment are “at risk”; developed glomeruli deep in the cortex were not affected. The glomerular abnormalities appear to be a direct consequence of premature birth and/or treatments in the postnatal care of the preterm neonate, since the number of abnormal glomeruli in the gestational control kidneys was negligible. Immunostaining with the endothelial cell marker CD31 showed that the abnormal glomeruli in the preterm kidneys were poorly vascularized, even though VEGF was expressed. The abnormal glomeruli appeared to be in a relatively immature state of development with a layer of WT-1-positive epithelial cells (indicative of podocytes) surrounding a spherical mass of relatively undifferentiated cells. Positive WT-1 immunostaining was also localized to the epithelial cells of Bowman’s capsule (parietal podocytes), which has been demonstrated previously in the human kidney (2). Interestingly, Bariety et al. (2) noted that capsules without a glomerular tuft, or a retracted tuft, contained a greater number of parietal podocytes compared with normal glomeruli lining the entirety of Bowman’s capsule. Furthermore, Gibson et al. (14) have also shown that in atubular cystic glomeruli in human kidneys, Bowman’s capsule is always lined by parietal podocytes. It is therefore conceivable that the cystic abnormal glomeruli observed in the preterm kidneys may be atubular, and as such would never be functional.

Not all kidneys from the premature baboons contained the same proportion of abnormal glomeruli, ranging from 0.2% to as high as 18%. Hence preterm birth may not always adversely impact kidney development, or alternatively there may be a difference in the rates of resorption of dysfunctional glomeruli (26). Another likely explanation is that factors in the postnatal care of the neonate (which varies between neonates) adversely impact nephrogenesis. In particular, pharmacological agents administered to the neonate in the postnatal period, such as aminoglycoside antibiotics, are known to be nephrotoxic (7, 15, 16). In the present study, since all preterm neonates were exposed to antibiotics after birth, it is possible that the glomerular abnormalities in the kidneys have been caused by exposure to nephrotoxic antibiotics. However, if this is the case, it is difficult to explain why there was such variation in the proportion of abnormal glomeruli within the preterm kidneys, given that all neonates received the same regime of antibiotics, except for two animals that were administered additional doses; these animals were not the neonates with the high proportion of abnormal glomeruli. Further studies are required to elucidate whether exposure to antibiotics is nephrotoxic to the preterm infant and/or whether other medications, or factors in the postnatal care of the preterm infants, lead to the adverse renal effects that we observe. If definitive associations are found, this may lead to potential interventions to improve the renal health of preterm babies.

In conclusion, using a non-human primate model the current study has clearly demonstrated ongoing nephrogenesis after preterm birth. The rate of glomerular formation remains similar following preterm birth; however, glomerular density (number of glomeruli per gram of kidney) was significantly reduced in the preterm kidney, suggesting that the non-glomerular compartments are growing at a faster rate. Of concern, many preterm neonates exhibited abnormal glomeruli in the outer renal cortex, suggesting that extrarenal nephrogenesis leads to an increased risk of abnormal glomerular development. Whether this will impact final nephron endowment is yet to be determined, since nephrogenesis was still ongoing.

ACKNOWLEDGMENTS

We thank the Southwest Foundation for Biomedical Research (San Antonio, TX) for provision of the baboon kidneys, in particular Jacqueline Coalson and Vicki Winter from the University of Texas Health Science Center for assistance in obtaining the kidneys. The authors also thank Alison Cox and Associate Professor Darren Kelly from the Department of Medicine at the University of Melbourne for assistance with the VEGF in situ hybridization.

GRANTS

This work was supported by National Institutes of Health BPD Resource Center Grant HL52636, P51RR13986 for facility support, and the National Health and Medical Research Council of Australia. L. Gubhaju and M. R. Sutherland were recipients of an Australian Postgraduate Award while undertaking this work.
