Submitted 22 July 2009; accepted in final form 30 November 2009

Jouret F, Walrand S, Parreira KS, Courtoy PJ, Pauwels S, Devuyst O, Jamar F. Single photon emission-computed tomography (SPECT) for functional investigation of the proximal tubule in conscious mice. Am J Physiol Renal Physiol 298: F454–F460, 2010. First published December 2, 2009; doi:10.1152/ajprenal.00413.2009.—Noninvasive analysis of renal function in conscious mice is necessary to optimize the use of mouse models. In this study, we evaluated whether single photon emission-computed tomography (SPECT) using specific radionuclear tracers can be used to analyze changes in renal proximal tubule functions. The tracers included 99mTc-dimercaptosuccinic acid (99mTc-DMSA), which is used for cortex imaging; 99mTc-mercaptoacetyltyglycine (99mTc-MAG3), used for dynamic renography; and 123I-β2-microglobulin, which monitors receptor-mediated endocytosis. 99mTc-DMSA SPECT imaging was shown to delineate the functional renal cortex with a ~1-mm spatial resolution and accumulated in the cortex reaching a plateau 5 h after injection. The cortical uptake of 99mTc-DMSA was abolished in Clcn5 knockout mice, a model of proximal tubule dysfunction. Dynamic renography with 99mTc-MAG3 in conscious mice demonstrated rapid extraction from blood, renal accumulation, and subsequent tubular secretion. Anesthesia induced a significant delay in the 99mTc-MAG3 clearance. The tubular reabsorption of 123I-β2-microglobulin was strongly impaired in the Clcn5 knockout mice, with defective tubular processing and loss of the native tracer in urine, reflecting proximal tubule dysfunction. Longitudinal studies in a model of cisplatin-induced acute tubular injury revealed a correlation between tubular recovery and 123I-β2-microglobulin uptake. These data show that SPECT imaging with well-validated radiotracers allows in vivo investigations of specific proximal tubule functions in conscious mice.

MATERIALS AND METHODS

TRANSGENIC MOUSE STRAINS are widely used to investigate the structure and function of developing and mature kidneys and to model human disorders. Thus far, functional studies into disease mechanisms essentially require animal death and ex vivo investigations that are potentially limited by various factors including low fertility rates, gender effects (e.g., X-linked transmission), or limited life span in some models. These restrictions complicate the design of intervention studies and require the development of large colonies, increasing costs and raising ethical questions. To circumvent some of these limitations, efforts are being made to develop in vivo functional imaging techniques in mice. In particular, the possibility to perform quantitative and/or dynamic molecular imaging studies using high-resolution positron emission tomography (PET) or single photon emission-computed tomography (SPECT) has emerged recently (23).

Among its numerous applications, SPECT may be useful for noninvasive investigation of renal function in the mouse by means of dynamic imaging, parenchymal scanning, and quantification of filtration, secretion, and reabsorption events (8). In particular, the possibility to use different radiotracers for SPECT imaging provides the opportunity to investigate various transport processes taking place in the proximal tubule (PT), a segment that plays a paramount role in homeostasis (Fig. 1). Diseases causing PT dysfunction are associated with life-threatening complications, including electrolyte and acid-base disorders, protein and amino acid imbalance, as well as abnormal handling of numerous endogenous and exogenous compounds.

To evaluate the technical possibilities of dynamic molecular imaging in vivo, we have used a SPECT system (26) to investigate the transport functions of the PT including apical and basolateral uptake and apical secretion. We evaluated these parameters in control mice, mice with restricted kidney infarction, and mice with congenital or acquired PT dysfunction (renal Fanconi syndrome). In particular, we used Clcn5 knockout (KO; Clcn5+/−) mice that are characterized by generalized PT dysfunction and low-molecular-weight (LMW) proteinuria due to defective receptor-mediated endocytosis (7) and represent a well-established model for Dent’s disease (28). We also used a mouse model of acquired, reversible PT injury induced by cisplatin (9) to evaluate the potential recovery over time.

To avoid the potential deleterious effects of general anesthesia, SPECT imaging was performed in conscious mice, using three well-established renal radionuclear tracers (Fig. 1). 99mTc-mercaptoacetyltriglycine (99mTc-MAG3), which is secreted into the urine following basolateral uptake by PT cells, is regarded as the best available tubular marker for dynamic renography (12). Dimercaptosuccinic acid (99mTc-DMSA), which accumulates in the renal cortex by a basolateral uptake in the epithelial cells lining the pars recta (S3 segment), is used for cortex imaging (16, 25). Finally, 123I-β2-microglobulin is a reference tracer for assessing the receptor mediated endocytosis of ultrafiltered LMW proteins by PT cells (7).

by clamping the superior pole of the organ for 30 min under anesthesia.
A model of partial or full recovery of acute PT injury was obtained by
a single injection of either vehicle (saline) or cisplatin (12
mg/kg BW ip) in C57 mice with follow-up for 2 wk (9). Mice were
housed individually in metabolic cages to assess overnight urine flow
rate and renal function during the cisplatin protocol. All procedures
were performed in accordance with National Institutes of Health
guidelines for the care and use of laboratory animals, and with the
approval of the Committee for Animal Rights of the Université
catholique de Louvain Medical School.

Radioisotopes. Human β2-microglobulin (β2M; Sigma, St. Louis,
MO) was iodinated with 123I-Na+ (GE Healthcare, Brussels, Bel-
gium) and iodobeads (Pierce, Aalst, Belgium) as previously described
(7) (purity in excess of 92% trichloroacetic acid-precipitable). Dimer-
captosuccinic acid (Technescan DMSA) or mercaptoacetyltriglycine
(Technescan MAG3) from Tyco HealthCare (Mechelen, Belgium)
were radiolabeled with 99mTc-Na-pertechnetate (Tyco HealthCare)
following the standard procedure. The physical half-life of 123I is 13
h and that of 99mTc is 6 h. Radiopharmaceutical purity was >99%,
as confirmed by instant thin-layer chromatography. All radiotracers
were diluted in saline (NaCl 0.9%) and injected (lateral caudal vein of
the tail iv) in a total volume of 150 μL.

SPECT system. The small-animal SPECT device (Linoview Sys-
tems, Amsterdam, The Netherlands) is made of four γ-detectors based
on pixilated CsI(Na) scintillators (5-mm thickness, 2.44 × 2.44-mm
crystal size). Detectors are fitted with a rake collimator equipped with
an adjustable slit aperture, made of two iridium square rods (2 × 2 ×
60-mm) (Supplemental Fig. 1; all supplementary material for this
article is available on the journal web site). The spatial resolution of
the system after reconstruction is 0.35 mm (26).

Acquisition procedure. In a preliminary experiment, dynamic
99mTc-MAG3 SPECT imaging was performed before and after anes-
thesia (ketamine, 100 μg/g, Merial, Brussels, Belgium; xylazine 10
μg/g, Bayer, Antwerp, Belgium) in two pairs of C57 mice. Subse-
quently, kinetic studies with the three radiotracers were performed on
conscious Clcn5 mice placed in a plastic holder to reduce animal
motion during imaging (Supplemental Fig. 1). The mice (pairs of
Clcn5 WT vs. KO) were studied over a total period of 8 wk, with three
sequential injections of DMSA, MAG3, and β2M on the same mice,
separated by a minimal interval of 5 days.

Static SPECT was obtained hourly (acquisitions of 5 min each)
during 5 h after intravenous (iv) injection of 700 μCi of 99mTc-DMSA
(3 pairs). At 6 h postinjection, a 30-min acquisition was per-
formed under anesthesia to obtain high-resolution images. In two pairs
of mice, the scanning was repeated 30 min after furosemide injection
(10 mg/kg BW ip; final volume: 30 μL). Continuous dynamic SPECT
(acquisitions of 15-s each) was achieved over 30 min after iv injection
of 600 μCi of 99mTc-MAG3 (n = 3 pairs) or 200 μCi 123I-β2-
microglobulin (n = 3 pairs), respectively. The linear motion of the
detectors was set in such a way that the four-slit apertures would draw
the narrowest rectangle possible around the animal. The distance between
the actual contours and the collimator aperture was typically
The linear acquisition generates linograms forming a complete set of tomographic data allowing the reconstruction of the activity map (27).

Data processing. Reconstructions were performed using the maximum-likelihood expectation maximization algorithm with attenuation correction but without scatter correction or spatial resolution recovery (11). Time-activity curves were generated, $^{99mTc}$-MAG3 dynamic parameters were calculated using a three-compartment model, by fitting the curves to two exponentials.

The glomerular filtration rate (GFR) of $^{123I}$-2-β2-microglobulin was assessed by fitting all the organ curves (heart, kidney, thyroid, liver, spleen, bladder) by a multicompartmental model (Supplemental Fig. 2). The GFR can be calculated as $\text{GFR} = k_i V_p$ (i), where $k_i$ is the glomerular uptake rate of the $^{123I}$-2-β2-microglobulin, and $V_p$ is the plasma volume. Only the interval from 30 to 180 s postinjection was considered to avoid the effects of dilution after bolus injection, as well as $^{123I}$-2-β2-microglobulin tubular reabsorption and metabolism, respectively. All kinetic parameters of renal uptake were calculated using SigmaPlot 2000 (Systat Software, Erkrath, Germany). The plasma volume of the mice was estimated based on blood volume (8% body wt) (20) and 0.45 as average hematocrit value for the mice.

Autoradiography. For autoradiography, kidneys were exsanguined in situ, removed 7 min after iv injection of 620 ng/g of body weight of $^{125I}$-2-β2-microglobulin, and fixed for 6 h at 4°C in 4% formaldehyde. Ten-micrometer sections were overlaid, treated with emulsion reagent (Ilford Scientific Product, Wilrijk, Belgium), and revealed after 1 mo.

Plasma and urine analyses. Urinary creatinine (modified Jaffé method) and albumin (turbimetric method) and plasma creatinine (enzymatic determination) were measured on a Synchron CX5 analyzer (Beckman Coulter, Brea, CA), following the manufacturer’s protocols (3). The urinary excretion of the LMW Clara cell protein (CC16, 16 kDa) was measured by radioimmunoassay (7).

Statistics. Results are expressed as means ± SD. Comparisons between $\text{Cln}5^{+/+}$ and $\text{Cln}5^{-/-}$ mice were made by Student’s unpaired $t$-tests assuming equal variance. The significance level was set at $P < 0.05$. Interassay variability was calculated as variation coefficient in 6 kidneys.

RESULTS

Imaging of the kidney cortex based on static $^{99mTc}$-DMSA uptake. $^{99mTc}$-DMSA is regarded as the ideal tracer for cortical imaging of the kidney. After uptake through the basolateral membrane, $^{99mTc}$-DMSA remains firmly bound to PT cells. We first investigated the spatial resolution of $^{99mTc}$-DMSA SPECT imaging of the kidney in wild-type (C57) mice. At 5 h postinjection, $^{99mTc}$-DMSA SPECT clearly delineated the functional renal cortex, whereas the medulla and the pelvis area (~1 mm) remained silent (Fig. 2A). The tracer uptake was

**Figure 2.** Single photon emission-computed tomography (SPECT) imaging of $^{99mTc}$-DMSA in mouse: perfusion (kidney infarction) and functional ($\text{Cln}5^{-/-}$ inactivation) defects. A and B: $^{99mTc}$-DMSA SPECT (A) in wild-type mice after apical infarction of the right kidney (R). Coronal (top) and transverse (bottom) slices show no activity in the infarction area (arrowheads). Bars = 3 mm. Histological examination after hematoxylin-eosin staining (B) confirms the infarction of the top right pole of the corresponding kidney (low magnification, top; high magnification, bottom). Bars = 3 mm (top) and 100 μm (bottom). C: kinetics of $^{99mTc}$-DMSA uptake in the kidney cortex measured using consecutive SPECT acquisitions ($n = 8$ kidneys from 4 mice). The asymptotic curve was fitted on the mean (red circle), and supports equilibrium (9.8 ± 0.4% of injected dose) at 5 h postinjection in $\text{Cln}5^{+/+}$ mice. SD is represented at each time point. Renal uptake of $^{99mTc}$-DMSA is abolished in $\text{Cln}5^{-/-}$ mice ($n = 8$ kidneys, blue square). D and E: representative coronal (D) and transverse (E) sections of $^{99mTc}$-DMSA SPECT imaging of $\text{Cln}5^{+/+}$ and $\text{Cln}5^{-/-}$ kidneys ($n = 6$ kidneys) before and after furosemide administration (10 mg/kg body wt ip). In $\text{Cln}5^{+/+}$ kidneys, the tracer is concentrated over the cortex area and insensitive to furosemide administration. In $\text{Cln}5^{-/-}$ mice, the $^{99mTc}$-DMSA signal is minimal, exclusively located in the pelvis, and rapidly cleared after furosemide injection. Dotted circles represent the cortical contours in $\text{Cln}5^{-/-}$ kidneys. Bars = 3 mm.
abolished over an apical area of experimental infarction, the boundaries of which correlated with the histopathological examination (Fig. 2, A and B).

The kinetics of in vivo 99mTc-DMSA uptake in wild-type (Cln5+/+ ) mice increased progressively to a plateau level of ~10% of the injected dose 5 h after injection (Fig. 2C; Table 1). The interassay variation coefficient (5.6%) demonstrated highly reproducible uptake measurements. Coronal and transverse sections evidenced the accumulation of 99mTc-DMSA in the cortex of Cln5+/+ kidneys, insensitive to furosemide (Fig. 2, D and E). In contrast, the cortical uptake of 99mTc-DMSA was abolished in Cln5−/− kidneys (Fig. 2, C and E; Table 1), with minimal activity in the pelvis that was cleared after furosemide injection.

These results demonstrate that 99mTc-DMSA SPECT imaging is able to delineate the functional renal cortex in the mouse, with a ~1-mm spatial resolution and a kinetics of uptake similar to the asymptotic curve observed in humans. Defective 99mTc-DMSA cortical imaging is observed in cases of defective perfusion (kidney infarction) or generalized dysfunction of PT cells (Cln5−/− mice).

Dynamic renography with 99mTc-MAG3. 99mTc-MAG3 is considered as the best tracer for dynamic imaging of the kidney. The tracer is concentrated in PT cells by basolateral boundaries of which correlated with the histopathological examination (Fig. 2, A and B). The renal handling of 99mTc-MAG3 uptake in wild-type (C57) mice is shown on Fig. 3. Ketamine-xylazine anesthesia induced a significant delay in 99mTc-MAG3 clearance, with a delayed and higher peak of uptake, as well as a higher degree of variability than in conscious mice. The dynamic renography in conscious Cln5 mice is shown on Fig. 4.

The SPECT imaging of 99mTc-MAG3 handling by wild-type Cln5+/+ kidneys is characterized by a rapid extraction from blood (T1/2IN, 0.4 ± 0.1 min), maximal renal accumulation between 90 and 120 s after iv injection (~12% of injected dose/kidney), and subsequent tubular secretion (T1/2OUT, 4.7 ± 0.5 min). Of note, the kinetic parameters of 99mTc-MAG3 handling are not significantly affected in Cln5−/− mice (Fig. 4; Table 1).

Renal handling of 123I-β2-microglobulin in Cln5 mice. β2-microglobulin is a 12-kDa protein that is ultrafiltered and completely reabsorbed via receptor-mediated endocytosis at the apical pole of PT cells. Monitoring the endocytic uptake of β2-microglobulin is thus considered as a faithful marker of the activity of PT cells (7). The dynamic SPECT imaging of 123I-β2-microglobulin handling by wild-type Cln5+/+ kidneys showed a rapid glomerular filtration followed by a progressive accumulation in the cortex, with maximal activity (6.4 ± 0.7% of injected dose/kidney) at 7 min postinjection (Fig. 5A; Table 1). The efficient breakdown of 123I-β2-microglobulin in PT cells was reflected by 123I reflux into the blood. The 123I

release of free123I into the blood. In the cortex, with subsequent washout corresponding to breakdown and further SPECT imaging vs. autoradiography. In each group. In autoradiography of kidneys fixed 7 min after injection of 125I-2-microglobulin, the quantitation of iodine-labeled B2-microglobulin in transverse kidney sections at 7 min postinjection in Clcn5 mice. The urinary excretion of 2-microglobulin in Clcn5V−/− mice, 123I-2-microglobulin is restricted to the cortex by SPECT, correlating with a segmental distribution along radial proximal tubules. In Clcn5V−/− mice, SPECT only detects activity in the pelvis without significant uptake in the cortex, as confirmed by the lack of autoradiographic signal. Dotted circles represent the cortical contours in Clcn5V−/− kidney. Bars = 5 mm (left) and 1 mm (right).

Fig. 5. Dynamic renal handling of β2-microglobulin in Clcn5 mice. The time-activity curves show the progressive uptake of 123I-β2-microglobulin following glomerular filtration and apical, receptor-mediated endocytosis by PT cells. The first part of the ascending curve corresponds to the progressive accumulation of the tracer in the urinary lumen (i.e., glomerular filtration), whereas accumulation beyond the first 3 min corresponds to apical endocytosis by PT cells. A: dynamic SPECT analysis 123I-β2-microglobulin in Clcn5V+/− (red circle) and Clcn5V−/− (blue cross) whole kidneys, and Clcn5V−/− cortex (blue square). The curves show the average of 6 kidneys (3 pairs of mice) in each group. In Clcn5V−/− mice, 123I-β2-microglobulin rapidly accumulates in the cortex, with subsequent washout corresponding to breakdown and further release of free 123I into the blood. In Clcn5V−/− mice, 123I-β2-microglobulin rapidly clears through the kidneys as a pure result of glomerular filtration. B: representative distribution of iodine-labeled β2-microglobulin in transverse kidney sections at 7 min postinjection in Clcn5V−/− and Clcn5V+/− mice: in vivo SPECT imaging vs. autoradiography. In Clcn5V+/− kidney, β2-microglobulin is restricted to the cortex by SPECT, correlating with a segmental distribution along radial proximal tubules. In Clcn5V−/− mice, SPECT only detects activity in the pelvis without significant uptake in the cortex, as confirmed by the lack of autoradiographic signal. Dotted circles represent the cortical contours in Clcn5V−/− kidney. Bars = 5 mm (left) and 1 mm (right).

present in Clcn5V+/− urine at 60 min postinjection was mostly free iodine (92 ± 2% of total urine activity, n = 3). In strong contrast, Clcn5V−/− kidneys showed a severe defect in the reabsorption of ultrafiltered 123I-β2-microglobulin (Fig. 5A; Table 1), with predominant urinary loss of intact 123I-β2-microglobulin (62 ± 4% of total urine activity, n = 3). The autoradiography of kidneys fixed 7 min after injection of 123I-β2-microglobulin, performed sequentially in the mice used for in vivo SPECT imaging, showed a strong cortical signal in Clcn5V−/− kidneys contrasting with the lack of tracer uptake in Clcn5V+/− kidneys (Fig. 5B). Importantly, the calculated glomerular filtration rate of 123I-β2-microglobulin (0.22 ± 0.02 ml/min), based on the first part of the curve (see Fig. 5A), was similar in both strains of Clcn5 mice. These data demonstrate that the congenital PT dysfunction caused by the lack of ClC-5 is adequately reflected by SPECT imaging of defective renal handling of β2-microglobulin.

Renal uptake of 123I-β2-microglobulin: recovery after cisplatin injury. We used a model of reversible tubular toxicity induced by cisplatin, to test the potential of SPECT to provide a longitudinal assessment of acquired PT dysfunction in individual mice. The PT dysfunction, evidenced by the urinary excretion of albumin (and that of CC16, data not shown), peaked at day 5 and showed progressive recovery thereafter (Fig. 6A). A similar profile was observed by sequential SPECT imaging of cisplatin-treated mouse kidneys (Fig. 6B). Importantly, the calculated glomerular filtration rate of 123I-β2-microglobulin (0.22 ± 0.02 ml/min), based on the first part of the curve (see Fig. 5A), was similar in both strains of Clcn5 mice. These data demonstrate that the congenital PT dysfunction caused by the lack of ClC-5 is adequately reflected by SPECT imaging of defective renal handling of β2-microglobulin.

Table 1). With predominant urinary loss of intact 123I-β2-microglobulin (0.07 ± 0.02 ml/min) and subsequently decreased toward normal values at day 11 (2.5 ± 1 µg/mg creatinine) and day 13 (3.8 ± 3.2 µg/mg creatinine) (*P < 0.05, at least 4 values/time point). ns, Not significant. Representative sequential SPECT imaging for 123I-β2-microglobulin handling in control mice (red circle) and cisplatin-treated mouse reveals defective endocytic uptake at day 5 (blue inverted triangle), with partial recovery at day 12 (blue triangle). Note that the excretion defect (curve >7 min) persists at day 12.
imaging for the renal uptake of \(^{123}\text{I}\)-\(\beta_2\)-microglobulin in individual mice, with a major defect of uptake at day 5 followed by partial recovery at day 12 (Fig. 6B).

**DISCUSSION**

This report demonstrates the feasibility and validity of both static and dynamic SPECT imaging to investigate specific PT functions in conscious mice. To the best of our knowledge, this is the first report of dynamic SPECT renography in conscious mice demonstrating the feasibility of continuous monitoring of drug handling from the time of iv injection.

Our studies of \(^{99m}\text{Tc}\)-MAG3 showed a delayed tracer clearance and wider intra-assay variability in anesthetized mice, confirming the adverse impact of ketamine/xylazine on baseline renal function (14, 21, 22, 29). To circumvent the need for anesthesia, we used a simple plastic holder, which was sufficient to immobilize the mice without discomfort during SPECT acquisition (Supplemental Fig. 1). The imaging of conscious mice allowed us to sequentially use three radioisotopes to assess distinct PT functions in the same mice: 1) uptake of \(^{99m}\text{Tc}\)-DMSA to evaluate the functional cortex with high resolution; 2) dynamic \(^{99m}\text{Tc}\)-MAG3 SPECT to investigate the basolateral capture and apical secretion; and 3) processing of \(^{123}\text{I}\)-\(\beta_2\)-microglobulin to assess apical receptor-mediated endocytosis.

We took advantage of the Cln5 KO mice (7, 18, 28) to provide a proof of concept for the use of SPECT, which showed a severe defect in both apical receptor-mediated endocytosis and basolateral anionic uptake, without significant alteration of the apical secretion by PT cells.

The renal uptake of \(^{99m}\text{Tc}\)-DMSA showed a progressive accumulation in mouse kidney cortex, matching standard curves reported in humans (16). At the plateau phase, \(^{99m}\text{Tc}\)-DMSA SPECT yields a millimetric delineation of the cortex, sufficient to identify a local area of parenchymal damage, as documented by the experimental infarction model (Fig. 2, A and B). The procedure has a low interassay variability, which supports its usefulness for repetitive and long-term biodistribution studies, as well as longitudinal studies (e.g., evaluation of toxicity following treatment) in the same mice.

The dynamic SPECT quantification of \(\beta_2\)-microglobulin renal uptake provided the first in vivo time course of PT receptor-mediated endocytosis in conscious mice. The radiolabeled LMW protein is freely filtered by the glomeruli, avidly captured in the renal cortex, and rapidly degraded with subsequent release of the radiotracer and residual peptide/amine acids to peritubular capillaries (2). The compartmental analysis of \(^{123}\text{I}\)-\(\beta_2\)-microglobulin biodistribution (Supplemental Fig. 2) enabled us to determine a GFR of 0.22 ± 0.02 ml/min, similar to that reported previously by using FITC-inulin clearance (20). The usefulness of SPECT to evaluate PT function is further demonstrated by the Cln5 KO mice, characterized by defective endocytosis due to the internalization of the multiligand receptors, megalin and cubulin (7, 18). Our data show that the defective PT apical endocytosis previously evidenced by ex vivo counting (7) is confirmed by noninvasive in vivo SPECT of \(^{123}\text{I}\)-\(\beta_2\)-microglobulin uptake. Despite similar GFR, the tubular reabsorption of \(^{123}\text{I}\)-\(\beta_2\)-microglobulin is strongly impaired in Cln5 \(^{5V/5}\) mice, with altered metabolism in PT and subsequent loss in the urine, mostly as native \(^{123}\text{I}\)-labeled protein.

Similarly to \(\beta_2\)-microglobulin, the renal handling of \(^{99m}\text{Tc}\)-DMSA has been regarded as an indicator of PT dysfunction in human and animal models (1, 25). For example, treatment of rats with Na-maleate induces a typical renal Fanconi syndrome, with marked reduction of \(^{99m}\text{Tc}\)-DMSA uptake (19). In our study, SPECT quantification of \(^{99m}\text{Tc}\)-DMSA capture shows that inactivation of Cln5 is associated with a lack of tracer accumulation in the renal cortex, suggesting a severe defect in PT basolateral function. It is likely that the residual signal detected in the pelvis of Cln5 \(^{5V/5}\) mice represents a small glomerular filtration of \(^{99m}\text{Tc}\)-DMSA (17). The basolateral uptake of \(^{99m}\text{Tc}\)-DMSA from peritubular capillaries into S3 PT cells is mediated by the Na\(^+\)/dicarboxylate cotransporter NaDC3 (SLC13A3) (4, 13) (Fig. 1). Of note, the coexpression of nonconducting fragments of CIC-5 with NaDC transporters alters their translation and/or trafficking in Xenopus laevis oocytes, resulting in decreased surface expression (15). The severe deficit in both apical and basolateral SPECT uptake reported here further demonstrates that the functional loss of CIC-5 induces a generalized intracellular trafficking in PT cells (7, 18).

Renal scintigraphy with \(^{99m}\text{Tc}\)-MAG3, a radiolabeled analog of p-aminohippurate, can provide excellent image quality even with severe renal failure (10). For instance, \(^{99m}\text{Tc}\)-MAG3 imaging detected changes in renal function in anesthetized mice as early as 5 h following ischemia-reperfusion injury (22). A model for \(^{99m}\text{Tc}\)-MAG3 secretion by PT cells has recently been proposed, based on in vitro transport experiments in X. laevis oocytes (24) (Fig. 1). \(^{99m}\text{Tc}\)-MAG3 is intracellularly accumulated through the basolateral organic anion transporter OAT1 that is expressed in all PT segments (4). The molecular counterpart of \(^{99m}\text{Tc}\)-MAG3 apical transport could involve the Na\(^+\)-dependent phosphate transporter NPT1 and/or the multidrug resistance protein MRP2 (5, 24). Our results demonstrate that PT dysfunction caused by the functional loss of CIC-5 is not associated with a defect in \(^{99m}\text{Tc}\)-MAG3 renal handling. The contrast between the complete loss of \(^{99m}\text{Tc}\)-DMSA basolateral uptake and the preserved \(^{99m}\text{Tc}\)-MAG3 secretion in Cln5 KO kidneys provides further evidence that these two pathways are functionally independent (24) and corroborates immunolocalization studies showing a distinct distribution of NaDC3 and OAT1 in PT segments (4). Additional SPECT studies using mouse models invalidated for distinct organic anion transporters may help establish the metabolic pathways handling these particular radioisotopes, as well as other drugs and metabolites.

In conclusion, SPECT analysis represents a new approach to characterize the renal PT function in conscious mice, based on acute and/or repetitive biodistribution studies using distinct radiolabeled tracers. Two limitations cannot be ignored. First, the spatial resolution of SPECT, being limited to the millimetric range, cannot compete with rapidly evolving live-microscopy methods (6). Second, although SPECT offers a temporal resolution of 5–10 s for pharmacokinetic studies, this may not be sufficient to explore faster functions such as organellar activation or intracellular trafficking. Nevertheless, the development of creative approaches dedicated to small-animal imaging will permit further functional investigations of transgenic mouse strains, with relevance for renal physiology or disease mechanisms.
