Rodan AR, Cheng C, Huang C. Recent advances in distal tubular potassium handling. Am J Physiol Renal Physiol 300: F821–F827, 2011. First published January 26, 2011; doi:10.1152/ajprenal.00742.2010.—It is well known that sodium reabsorption and aldosterone play important roles in potassium secretion by the aldosterone-sensitive distal nephron. Sodium- and aldosterone-independent mechanisms also exist. This review focuses on some recent studies that provide novel insights into the sodium- and aldosterone-independent potassium secretion by the aldosterone-sensitive distal nephron. In addition, we discuss a study reporting on the regulation of the mammalian potassium kidney channel ROMK by intracellular and extracellular magnesium, which may be important in the pathogenesis of persistent hypokalemia in patients with concomitant potassium and magnesium deficiency. We also discuss outstanding questions and propose working models for future investigation.

aldoosterone; intercalated cell; maxi-K; ROMK; WNK1

The aldosterone-sensitive distal nephron, comprising the late distal convoluted tubule, the connecting tubule, the cortical collecting duct, and to a lesser extent the medullary collecting duct, determines the final urinary potassium content and therefore regulates total body potassium homeostasis (41). A major mechanism for potassium secretion in this part of the nephron is the generation of a lumen-negative potential by the reabsorption of sodium through the apical epithelial sodium channel (ENaC). Together with the activity of the basolateral Na-K-ATPase, which transports potassium into tubular epithelial cells against a concentration gradient, sodium reabsorption through ENaC generates the electrochemical gradient for potassium secretion. Aldosterone stimulates this pathway by increasing the activity and density of ENaC and Na-K-ATPase. However, while elevation in aldosterone is necessary for maximal potassium excretion, there are clearly aldosterone-independent mechanisms for potassium excretion (12, 26, 63, 78, 81).

In this review, we will discuss recent studies providing novel regulatory mechanisms by which this may occur. Space restrictions prevent a comprehensive review of all studies devoted to distal potassium handling; the reader is referred to recent reviews that discuss other aspects of this process (37, 73, 75, 80).

Sodium-Independent Potassium Secretion

A recent paper by Frindt and Palmer (15) provides new insights into the relative role of sodium-independent potassium secretion. Rats were administered acute intravenous infusions of amiloride to achieve tubular concentrations sufficient to block >98% of apical ENaC. Under control conditions, this completely abolished potassium secretion. As rats were fed increasing amounts of potassium, however, an ENaC-independent (i.e., amiloride-insensitive) potassium secretory pathway was revealed. In fact, a relatively modest increase in potassium ingestion, from 0.6 to 0.9%, was sufficient to increase sodium-independent potassium secretion (15). These results are consistent with the findings of Muto et al. (42), in which removal of luminal sodium from the perfusate of isolated perfused rabbit cortical collecting duct decreased, but did not abolish, potassium secretion.

What are the mechanisms for sodium-independent potassium secretion? Frindt and Palmer (15) discussed several possible mechanisms. One of these is the above-mentioned report by Muto et al. (42) showing that basolateral Na+/H+ exchangers operate along with Na-K-ATPase to recycle sodium and allow potassium secretion in the absence of luminal sodium. This mechanism presumably operates in principal cells. Additional possibilities for sodium-independent potassium secretion have emerged from subsequently published papers. This review focuses on recent studies implicating the role of intercalated cells in this process.

Role of intercalated cells: BK, Kv1.3, and chloride channels.

One possibility is that transcellular potassium secretion occurs through intercalated cells, in which apically located potassium...
channels are electrically coupled to apical chloride channels (see Fig. 1). Palmer and Frindt have estimated the apical membrane potential of intercalated cells to be \( \sim 0 \) mV (50). In this case, the electric driving force for potassium secretion is greater than across the apical membrane of the principal cell, in which the membrane potential of approximately \(-80\) mV must be compensated for by the large transepithelial potential generated by sodium reabsorption through ENaC. In addition, the relatively depolarized membrane potential of the intercalated cells increases the open probability of voltage-gated potassium channels. One of these, the large-conductance, calcium-activated potassium channel, known as BK or maxi-K, has been appreciated to play a role in renal potassium secretion for some time, and in vivo studies have confirmed its role in renal potassium excretion (2, 22, 52, 53, 56). Although there is some controversy regarding whether BK is acting in principal cells, intercalated cells, or both, it is clearly found at high density in intercalated cells in both the connecting tubule and the cortical collecting duct of the rat (13, 47, 50), and mRNAs of BK channel subunits are upregulated in intercalated cells of rabbits on a high-potassium diet (43). Interestingly, iberiotoxin-inhibitable, BK-dependent potassium secretion in the rabbit cortical collecting duct was decreased but not abolished under conditions of no luminal sodium (42). This suggests that BK-dependent potassium secretion can also occur by both sodium-dependent and -independent mechanisms.

A second voltage-gated potassium channel that is expressed on the apical surface of intercalated cells, Kv1.3, has recently been described by Carrizoza-Gaytan et al. (6). In rats fed a high-potassium diet, apical expression of Kv1.3 is seen in \( \alpha \)-intercalated cells, and decreased potassium secretion is observed with luminal perfusion of margatoxin, a Kv1.3 inhibitor, in isolated cortical collecting ducts from these rats (6). Further experiments are needed to better define the importance of this channel. For example, can Kv1.3 currents be identified in intercalated cells in which BK (which may otherwise mask the Kv1.3 currents) has been inhibited? Can a role for Kv1.3 be uncovered in tubules from ROMK knockout mice treated with iberiotoxin (a BK inhibitor)? A previous study showed that in these mice, potassium secretion in the late distal tubule was abolished, suggesting that ROMK and BK comprise the entire exit pathway for apical potassium secretion (2). However, these mice were not studied under high-potassium conditions, and it is also possible that Kv1.3 may play a role in tubular sites that were not studied in these micropuncture experiments.

While the depolarized apical membrane potential of intercalated cells provides an attractive explanation for the activity of BK and Kv1.3 (which are relatively quiescent in hyperpolarized membrane potentials), it does not explain the potential sodium independence of this process. Potassium secretion across the apical membrane hyperpolarizes the membrane potential and diminishes the driving force for further secretion. Sodium reabsorption via ENaC provides a sustained driving force for potassium secretion in principal cells. One hypothesis for sodium-independent potassium secretion in intercalated cells lacking ENaC is that apical potassium secretion is electrically coupled to apical chloride secretion. In both rabbits (77) and rats (69), decreasing tubular luminal chloride concentration increases potassium secretion. A study by Fernandez et al. (11) suggests that an apical chloride channel may be present on the surface of intercalated cells. Such a channel has not been electrophysiologically characterized in native tubules but has been studied in a renal cultured cell line derived from cortical collecting duct with intercalated cell characteristics (9, 33, 61). The molecular identity of this channel is unknown. Intriguingly, a family of calcium-activated chloride channels, the TMEM16 proteins, has recently been identified (18). Like BK, these channels are both calcium sensitive and voltage dependent and thus could conceivably be activated under the same conditions as BK. TMEM16 channels have been recently shown to play a role in epithelial ion transport (10, 30, 46, 60). mRNA for some family members has been demonstrated in the mouse kidney (60), but these channels have not otherwise been studied in the kidney.

One problem with the hypothesis that transepithelial potassium secretion occurs via intercalated cells, however, is that the mechanism for basolateral potassium uptake is unclear. Studies measuring ouabain-sensitive current (50), or using electron microprobe (59) or energy-dispersive X-ray microanalysis (4) of freeze-dried cryosections, are consistent with only low levels of Na-K-ATPase activity in intercalated cells compared with principal cells. Whether Na-K-ATPase activity increases in intercalated cells in animals on a high-potassium diet has not been studied, although by immunohistochemistry expression of

![Fig. 1. Model of intercalated cell potassium secretion. Due to a large basolateral chloride conductance (not shown), the basolateral membrane potential (\( V_{bl} \)) of the intercalated cell is close to the equilibrium potential for chloride, approximately \(-36\) mV. Due to electrogenic sodium reabsorption through the epithelial sodium channel (ENaC) in neighboring principal cells (not shown), a transepithelial potential (\( V_{TE} \)) is generated. If this is about the same as \( V_{bl} \), the apical membrane potential (\( V_a \)) of the intercalated cell will be \(-0\) mV (see Ref. 50 for a more detailed discussion). This relatively depolarized \( V_a \) results in a higher open probability for the voltage-gated potassium channels BK and Kv1.3 and provides a strong electric driving force for potassium secretion. By coupling potassium secretion to chloride secretion, a sodium-independent component of potassium secretion can be achieved. An apical chloride channel has yet to be identified, but an attractive hypothesis is that a member of the voltage- and calcium-dependent TMEM16 family could provide this function. On the basolateral side, potassium uptake may occur through the Na-K-ATPase, but because this is present at only low levels in intercalated cells, additional uptake may occur through Na\(^+\)-K\(^+\)-2Cl\(^-\) cotransporter isoform 1 (NKCC1). If Na-K-ATPase is limiting, the cotransported sodium could be recycled either through the ouabain-insensitive Na-ATPase, or through other unidentified mechanisms, such as a Na-HCO\(_3\) cotransporter (not shown).]

Na-K-ATPase in intercalated cells of mice fed a high-potassium diet is low (27). An interesting possibility is that Na\(^+\)-K\(^+\)-2Cl\(^-\) cotransporter isof orm 1 (NKCC1) could serve in this role. A recent abstract reports that iberiotoxin-sensitive, flow-stimulated potassium secretion in rabbit isolated perfused cortical collecting duct was abolished by the basolateral application of bumetanide or removal of basolateral chloride (34). This is similar to the physiology of the distal colon, in which potassium secretion is thought to occur via basolateral uptake of potassium by NKCC1, followed by apical secretion through BK channels (62). NKCC1 is expressed on the basolateral membrane of rat intercalated cells in the medulla (19). Whether it is expressed at significant levels on the basolateral membrane of intercalated cells in the cortical collecting duct or connecting tubule under high-potassium conditions is unknown. Nonetheless, it is intriguing that knockout mice lacking NKCC1 have higher serum potassium concentrations than wild-type controls (71). A demonstration that sodium-independent potassium excretion is impaired in these mice, and that potassium secretion in isolated perfused cortical collecting tubules is decreased, would provide further support for a role for NKCC1. However, given the low intercalated cell Na-K-ATPase activity, this raises the question of how the sodium cotransported with potassium would be recycled across the basolateral membrane. One possibility is through the ouabain-insensitive Na-ATPase. In a recent study, this activity was observed in intercalated cell-like MDCK C11 cells at levels similar to those seen for the ouabain-sensitive Na-K-ATPase found in principal cell-like MDCK C7 cells (58). The molecular identity of this ATPase is unknown. Clearly, further studies are needed to clarify the molecular mechanisms by which intercalated cells may be involved in potassium secretion; Fig. 1 provides a hypothetical model that may serve as a basis for future experiments.

**Role for BK in intercalated cell shrinkage and modulation of fluid dynamics.** Holtzclaw et al. (28) propose an entirely different mechanism by which BK in intercalated cells may enhance potassium secretion. First, studying MDCK C11 cells, which like murine intercalated cells express the BK-α and β4 subunits, they found that shear stress results in the loss of intracellular cations and cell shrinkage in a BK-dependent process. This is explained by potassium efflux through the apical membrane under conditions of shear stress, which activates BK; due to the low levels of basolateral Na-K-ATPase, the cells cannot restore intracellular potassium and cell volume (28). Next, the authors examined a role for this process in vivo by studying BK-β4 knockout mice. When fed a high-potassium diet, wild-type mice had increased urinary flow. While Na-K-ATPase expression in principal cells was upregulated under these conditions, immunostaining was barely detectable in intercalated cells. Consistent with the authors’ findings in cultured cells, intercalated cells in the potassium-adapted wild-type animals underwent shrinkage, presumably in response to BK activation by increased distal flow, thereby increasing the cross-sectional area of the connecting tubule and collecting duct. In contrast, in the β4 knockout mice, the intercalated cells did not shrink, and the cross-sectional areas of the connecting tubule and collecting duct increased to a lesser degree than seen in wild-type mice. The authors propose that this could alter fluid dynamics in the distal tubule such that potassium secretion is impaired, thereby explaining the increased plasma potassium concentration and decreased fractional excretion of potassium observed in the knockout mice (27).

**Coordinated Roles of NCC and ROMK in Regulation of Potassium Secretion**

**Effects of dietary potassium on NCC and ROMK.** It has long been appreciated that an acute infusion of potassium chloride decreases sodium and fluid reabsorption in the proximal tubule (5), and a high-potassium diet decreases sodium and fluid reabsorption in the loop of Henle (3, 25, 64, 66). These effects in the proximal segments will tend to stimulate distal potassium secretion. A high-potassium diet also has direct effects on the distal tubule to modify potassium transport. Wang et al. (72) showed that a high-potassium diet increased the density of the apical small-conductance potassium channel SK, the native ROMK channel, in rat cortical collecting tubule. Subsequent studies showed that both long-term (12–16 days) (48) or short-term (6 or 48 h) (51) exposure to a high-potassium diet increased SK density in rat cortical collecting tubule. In a recent paper, Frindt and Palmer (17) have updated these findings using an inhibitor of ROMK, tertiapin-Q (TPNQ), which does not inhibit the closely related inwardly rectifying potassium channels Kir4.1 and Kir5.1 found on the basolateral membrane of tubular epithelial cells. This allowed the authors to accurately measure ROMK activity in rat connecting tubule and cortical collecting duct under whole-cell clamp conditions. This overcomes some of the obstacles of estimating the whole-cell density of channels using the cell-attached patch technique, which is subject to sampling errors due to nonrandom distribution of channels. They found that a high-potassium diet increased ROMK current by approximately threefold in both the connecting tubule and cortical collecting duct. Conversely, a low-potassium diet decreased ROMK current by 35% in the cortical collecting duct and by 50% in the connecting tubule. ROMK currents were similar in the connecting tubule and cortical collecting tubules from rats on a high-potassium diet, and a current was also detected in the outer medullary collecting duct under these conditions (17). This study helps resolve conflicting data from previous studies with regard to the effects of changes on dietary potassium in the connecting tubule vs. collecting duct (1, 13, 51, 74).

Using a different approach, in situ biotinylation, the same authors examined cell surface ROMK in rats fed low- or high-potassium diets. While total ROMK expression was decreased with a low-potassium diet and increased with a high-potassium diet, surface expression was altered (increased) only by a high-potassium diet (14). In addition, as expected, ENaC levels were generally increased with a high-potassium diet and decreased with a low-potassium diet. Interestingly, surface levels of NCC were decreased in rats fed a high-potassium diet (14). A decrease in sodium reabsorption via NCC would allow increased sodium reabsorption via ENaC, thus enhancing potassium secretion. This effect of potassium loading is in contrast to that of a low-sodium diet, in which surface levels of both ENaC and NCC were increased (16). Thus two maneuvers which increase serum aldosterone levels, that is, increased dietary potassium or decreased dietary sodium, have similar effects on ENaC but opposite effects on NCC.

A study by Vallon et al. (67) further supports the importance of coordinated regulation of NCC and ROMK for the renal process.
potassium homeostatic response to variations in dietary potassium intake. Vallon et al. showed that a low-sodium diet increased NCC expression, whereas a high-potassium diet decreased it. These investigators also examined phosphorylation of NCC at amino acids known to be important for cotransporter activation (55). Phosphorylation was increased by a low-sodium diet, consistent with cotransporter activation, and decreased by a high-potassium diet, consistent with cotransporter inhibition. Furthermore, the effects of dietary sodium and potassium were dissociated at the level of intracellular signaling. In mice lacking serum- and glucocorticoid-inducible kinase 1 (Sgk1), a known mediator of aldosterone action (68), the upregulation of NCC by a low-sodium diet was attenuated, whereas downregulation of NCC by high potassium diet was intact in the knockout mice (67). Together with the facts that a high-potassium diet increases serum aldosterone levels and aldosterone upregulates rather than downregulates NCC, this result supports that NCC regulation in response to dietary potassium intake is independent of aldosterone. This is reminiscent of ROMK, in which channel density is increased by a high-potassium diet, but not by exogenous aldosterone infusion or aldosterone induction by a low-sodium diet (48, 49, 51).

Role for WNK1 in regulation of NCC, NKCC2, and ROMK. What is the mechanism of aldosterone-independent up- and downregulation of ROMK and NCC, respectively, in a high-potassium diet? Recent studies suggest that the with-no-lysine kinase WNK1 may be important. WNK1 is mutated in pseudohypoaldosteronism type II, an autosomal dominant disorder in which patients are invariably hyperkalemic (76). In the kidney, two alternative transcripts of WNK1 are expressed, a full-length transcript called long WNK1 (L-WNK1), and a shorter, kidney-specific transcript lacking the kinase domain (KS-WNK1) (8, 45). In *Xenopus laevis* oocytes and cultured cells, L-WNK1 decreases surface ROMK expression by stimulating clathrin-dependent endocytosis, and KS-WNK1 inhibits this activity of L-WNK1 in a dominant-negative fashion (7, 24, 32, 70). In *X. laevis* oocytes and cultured cells, L-WNK1 upregulates the surface expression of NCC (55, 65). KS-WNK1 antagonizes the effect of L-WNK1 on NCC (65). These results raise the possibility that changes in dietary potassium may affect the ratio of L-WNK1 over KS-WNK1 to regulate ROMK and NCC. In support of this hypothesis, several groups have shown that the ratio of L-WNK1 to KS-WNK1 is decreased in animals fed a high-potassium diet and increased in animals fed a low-potassium diet (32, 44, 70). Levels of KS-WNK1 appear more sensitive to modulation by dietary potassium than levels of L-WNK1, and a high-potassium diet appears to be a more powerful regulator than a low-potassium diet (32, 44, 70). This is consistent with the greater changes in ROMK density seen with a high-potassium diet than with a low-potassium diet, as found in the analysis by Frindt and Palmer (17).

Three recent papers examine a role for KS-WNK1 in vivo. Liu et al. (35) generated transgenic mice overexpressing KS-WNK1 in renal tubular epithelial cells. As expected from the oocyte and cell culture studies described above, immunofluorescent staining of ROMK was higher in the KS-WNK1-overexpressing mice. Furthermore, the transgenic mice had lower serum potassium concentrations and higher fractional excretion of potassium, consistent with increased renal potassium clearance (35). In a separate study, Liu et al. (37) further showed that transgenic mice overexpressing KS-WNK1 in renal tubular epithelia have decreased NCC and NCC phosphorylation, as well as decreased thick ascending limb NKCC2 and phospho-NKCC2. Based on cell culture and oocyte studies, the decreased NCC and NKCC2 phosphorylation would be predicted to decrease cotransporter activity in both cases (54, 55). Functionally, this manifests as sodium wasting when the mice are placed on a low-sodium diet. The same authors generated KS-WNK1 knockout mice and found that knockout mice have increased NCC, phospho-NCC, NKCC2, and phospho-NKCC2, retaining sodium when on a high-sodium diet (37). Although renal potassium handling was not examined in detail, these mice become hyperkalemic when fed a high-potassium diet (36).

Hadchouel et al. (23) have also generated a KS-WNK1 knockout mouse and found increased expression of NCC and phospho-NCC in these mice. However, Hadchouel et al. reported that serum potassium levels between knockout and wild-type mice were not different. Reasons for the apparent differences between the two KS-WNK1 knockout models are unknown. Extra- and/or intrarenal compensatory responses, such as upregulation of BK (23), may be contributory.

![Fig. 2. Integrated regulation of potassium secretion by WNK1. A high-potassium diet decreases the ratio of full-length L-WNK1 to the kidney-specific transcript KS-WNK1, which lacks the kinase domain and inhibits L-WNK1 in a dominant-negative fashion. This occurs by upregulation of KS-WNK1 and downregulation of L-WNK1 by a high potassium diet. As a result, NKCC2 and Na^+/-Cl^- cotransporter (NCC) levels and activity are downregulated. This results in decreased sodium reabsorption in the thick ascending limb of the loop of Henle and the distal convoluted tubule, nphron segments in which electroneutral sodium and chloride reabsorption occurs. Increased sodium is therefore delivered to the downstream aldosterone-sensitive distal nephron, providing additional sodium for electrogenic reabsorption. This allows a more negative transepithelial voltage to develop and increases the driving force for potassium secretion. The decrease in the ratio of L- over KS-WNK1 may increase the level of ROMK, allowing greater potassium secretion across the apical membrane of principal cells in the aldosterone-sensitive distal nephron (connecting tubule, collecting duct). Flow-dependent potassium secretion, for example by BK, is also stimulated by the increased distal flow. The role of WNK1 in BK, Kv1.3 channels and potassium secretion through intercalated cells remains unexplored.](http://apjrenal.physiology.org)
Based on combined information from cell culture and in vivo studies, we propose the following model for future investigation (Fig. 2). A high-potassium diet decreases the ratio of L- to KS-WNK1. A decrease in the ratio of L- to KS-WNK1 decreases sodium reabsorption by the thick ascending limb of the loop of Henle and the distal convoluted tubule, thereby increasing sodium delivery and flow to the connecting and cortical collecting tubules and enhancing potassium secretion by these segments. The decrease in the ratio of L- to KS-WNK1 may also directly increase ROMK levels on the apical membranes of these epithelial cells, allowing increased potassium secretion. A low-potassium diet increases the ratio of L- to KS-WNK1 to regulate ROMK and NCC in the opposite direction. Thus modulation of the ratio of L- to KS-WNK1 may provide integrative control of potassium secretion by affecting the activity of several channels and transporters across multiple segments of the nephron. Future studies will include direct assessment of the effects of changing levels of KS-WNK1 and/or L-WNK1 on ROMK function and renal potassium handling using in vitro microperfusion of isolated tubules and/or patch-clamp recording of native tubules. Other future studies include examination of whether KS-WNK1 regulates NCC and ROMK by antagonizing L-WNK1 in vivo and elucidation of the mechanisms by which dietary potassium regulates levels of KS-WNK1 and L-WNK1. Finally, many studies have shown that WNK4 regulates ROMK and NCC (reviewed in Refs. 57, 73, and 75). The role of WNK4 in the dietary regulation of potassium handling warrants future studies.

Regulation of ROMK by Intracellular and Extracellular Magnesium

Hypokalemia is a very common electrolyte disorder in clinical medicine and is frequently associated with magnesium deficiency. Hypokalemia associated with magnesium deficiency is refractory to treatment by potassium replacement unless the concomitant magnesium deficiency is corrected. How magnesium deficiency exacerbates hypokalemia is unexplained. ROMK is an inwardly rectifying potassium channel of which outward potassium fluxes through the channel are inhibited by intracellular magnesium (38). The affinity for inhibition of ROMK by intracellular magnesium is modulated by membrane potentials and extracellular potassium concentrations. Based on predicted membrane potentials and extracellular potassium concentrations, the role of WNK4 in the dietary regulation of potassium handling warrants future studies.
