MEMBERS OF THE EPIDERMAL GROWTH factor (EGF) family are small mitogenic proteins involved in a number of mechanisms such as normal cell growth and differentiation. Their effects are mediated via autocrine, paracrine, or endocrine mechanisms. ErbB receptors have been recognized as targets in anticancer therapy and are now used in the treatment of breast and colon malignancies (93). The name and gene symbol ErbB (Table 1) was derived from a viral oncogene to which these receptors are homologous: erythroblastic leukemia viral oncogene. Multiple epithelial cancers, including kidney carcinoma, are associated with the EGFR-EGF axis (61, 73, 111, 134). In addition to cancer biology, EGF receptor (EGFR) activation is critical in acute kidney injury (AKI) and chronic kidney diseases (CKD; Refs. 71, 108, 130). Here we discuss recent results supporting functional interactions between EGF-family proteins and blood pressure control in the kidney, as well as provide details of some mechanisms underpinning such interactions and the clinical consequences of these modulations. Particular emphasis is placed onto the mechanisms of regulation of sodium transport in the kidney by the EGF family growth factors. Hence we aim to provide critical insight into the physiological control of kidney function by EGF and its related growth factors.

ErbB Receptors

The EGFR family, also known as ErbB receptors (91), consists of four transmembrane receptors that belong to the receptor tyrosine kinase superfamily and includes EGFR (ErbB1/HER-1), ErbB2 (neu/HER-2), ErbB3 (HER-3), and ErbB4 (HER-4). EGFR as well as other receptors in this family is a transmembrane receptor that consists of an extracellular domain with conserved two cysteine-rich domains necessary for ligand binding; a single membrane-spanning domain, which has a passive role in signaling and functions as an “anchor” of receptor in plasma membrane (53), and a cytoplasmic protein tyrosine kinase domain, where six tyrosine autophosphorylation sites are located (Fig. 1). After ligand binding, ErbB receptors dimerize, which is a required critical step for intrinsic receptor tyrosine kinases to be activated and thereby specific tyrosine-containing residues to become autophosphorylated (12). Phosphorylated ErbB receptors can recruit different adapter proteins with Src homology domain-2 (SH2) or phosphotyrosine binding domains (PTB; Ref. 8). Signals from dimerized, activated ErbB receptors lead to activation of multiple intracellular signal transduction pathways. Depending on the pairing of ErbB family receptors (homodimers or heterodimers; Fig. 1), there can be downstream stimulation of different combinations of signaling pathways (43).

To some extent, EGFR is expressed in every nephron segment. Although EGFR is the predominant ErbB receptor found in the normal adult mammalian kidney tubule, ErbB2, ErbB3, and ErbB4 are also expressed in the kidney but mainly localize to the distal and connecting tubules and collecting ducts (87, 130, 131, 133). Figure 2 demonstrates representative immunohistochemical staining for ErbB2 receptor in the kidney cortex of Sprague-Dawley rat. A number of various mechanisms control ErbB receptors trafficking and degradation (64, 99) as well as polarized distribution (18, 127) in the renal epithelial cells.
In the kidney and hypertension, the expression and function of ErbB receptors is crucial. ErbB receptors are a family of tyrosine kinase receptors that are activated by specific ligands, which trigger intracellular signaling pathways. These pathways are involved in various physiological processes, including cell growth, proliferation, and apoptosis. The regulation of ErbB receptors is controlled by their gene expression, protein synthesis, and cellular localization. The gene expression of ErbB receptors is tissue-specific and can be disrupted under pathological conditions, such as renal injury or disease. The protein synthesis and cellular localization of ErbB receptors are also regulated by various factors, including growth factors, cytokines, and extracellular matrix proteins. The activation of ErbB receptors is crucial for the maintenance of physiological processes, but excessive activation or mislocalization can lead to pathological conditions, such as kidney disease. Therefore, understanding the regulation and function of ErbB receptors is essential for developing targeted therapies for kidney diseases.
delays the progression of, and may even reverse, hypertension and diabetic nephropathy (125).

Activation of ErbB receptors by binding to their ligands promotes several biological responses. The physiological role of ErbB receptors is well established, especially in cancer. What is more, the role of ErbB-family members in renal development, physiology, and pathophysiology is also well recognized (130). Under physiological conditions, ErbB activation appears to play an important role in the regulation of renal hemodynamics and electrolyte handling by the kidney, while in different pathophysiological states ErbB activation may mediate either beneficial or detrimental effects to the kidney (130). ErbB signaling is critically involved in cell signaling, cell growth, proliferation, and renal electrolyte homeostasis. Once activated by site-specific phosphorylation, ErbB receptors serve as molecular integrators through either direct phosphorylation of target molecules or by serving as scaffolds for adaptor proteins. The great diversity of ligands and receptor dimer pairs allows activation of numerous signaling pathways that coordinately regulate complex processes including developmental growth control and adult homeostasis.

Effects of EGF-Family Members in the Kidney

The involvement of EGFR signaling in AKI and CKD development has been recently thoroughly reviewed (108). Although the precise mechanisms underlying effects of EGF signaling are not completely clear, numerous studies evidence abnormal EGF-EGFR axis functionality during progression and development of these diseases. Changes in EGFR expression and EGFR phosphorylation were detected in a variety of experimental models of AKI (15, 41, 44, 108) and CKD (16, 42, 56, 63, 109). Pivotal role of HB-EGF expression and EGFR signaling is also demonstrated in rapidly progressive glomerulonephritis (10, 31); abnormalities of apico-basal polarity and expression of EGF-EGFR axis were also described in the PKD epithelia (68, 126, 133).

What is more, EGF-family growth factors are involved in regulation of various epithelial ion channels in the kidney. For instance, EGF stimulates store-operated Ca\textsuperscript{2+} channels in human mesangial cells through an intracellular signaling mechanism involving tyrosine kinase and PKC (66). Later it was shown that EGF activates store-operated Ca\textsuperscript{2+} channels by a PLC-dependent, but inositol 1,4,5-trisphosphate receptor-independent, pathway (60). Polycystin-2, critical in PKD, can be also activated in response to EGF in the kidney epithelial cells (67). The physiological relevance of EGF-induced activation of TRPP2 was supported by animal studies in which homozygous deletion of the Egfr gene resulted in cystic dilatation of collecting ducts (112, 113). A role for ErbB receptor activation in the regulation of Mg\textsuperscript{2+} channels in the kidney has also been demonstrated. Genetic analysis has revealed that the melastatin transient receptor potential 6 (TRPM6) channel is mutated in patients with primary hypomagnesemia and secondary hypocalcemia (92, 122). Furthermore, the direct effects of EGF on TRPM6 channels were reported (46, 47, 110) and it was demonstrated that the EGFR inhibitor erlotinib is capable of affecting TRPM6 regulation and thereby altering Mg\textsuperscript{2+} handling in vivo (22).

diseases including hyper- and hypotension. For at least two decades, EGF has been known to regulate ENaC-mediated sodium transport. It was previously shown that EGF decreases active sodium transport in the isolated and perfused rabbit CD (75, 119, 120, 123) and immortalized epithelial cells (25, 26, 37, 94). Interestingly, EGF-family members cause a biphasic response of ENaC. EGF transiently increases sodium transport in Xenopus laevis kidney A6 cells in a phosphatidylinositol 3-kinase-dependent manner, and this stimulation is mediated by the inhibition of the MAPK pathway (70). Later it was reported that acute treatment with EGF and TGF-α enhanced ENaC activity in A6 cells by affecting channel open probability via phosphatidylinositol 3-kinase signaling pathway (62). However, the same study demonstrated that continuous treatment with EGF and TGF-α inhibited ENaC activity by decreasing the number of channels in the plasma membrane through MAPK1/2 pathways (62). Our data are also consistent with the idea that EGF-family members have a biphasic effect on sodium absorption in the mammalian kidney (59). Four members of the EGF-family (EGF, TGF-α, HB-EGF, and amphiregulin) were tested in cultured mpkCCDc14 principal cells. Basolateral addition of growth factors to these cells initially increased Na+ reabsorption above basal levels in a time-dependent manner. A significant increase was detected after 30 min, the earliest time point measured, with a maximum reached by 2 h. After 4 h of treatment, a slow and continuous decrease of ENaC-mediated transepithelial current was observed. Thus chronic treatment of monolayers with EGF-family growth factors leads to significant inhibition of ENaC-mediated current (59).

EGF-family ligands, as many other signaling molecules, activate corresponding receptors in a dose-responsive manner. Thus establishing the dose-response curves for the effects of EGF and other members of this family is critical for understanding physiological role of these growth factors. As we previously demonstrated, using immortalized mouse mpkCCDc14 principal cells, both EGF and TGF-α dose dependently modulated ENaC activity. The EC50 value for EGF activation (acute phase) was 3.7 ± 1.5 ng/ml. Chronic treatment with various concentrations of EGF (0.1, 0.5, 1, 10, and 100 ng/ml) and TGF-α (0.5, 1, 10, and 100 ng/ml) also resulted in dose-dependent decreases in ENaC-mediated transepithelial current (59). Liu et al. (62) also reported that EGF-family ligands have dose-dependent biphasic effects on amphibian A6 cells. Both TGF-α and EGF chronically decreased sodium transport in a dose-dependent manner. The IC50 was 4.7 ng/ml for TGF-α-induced inhibition and 110 ng/ml for EGF-induced inhibition (62). A number of studies analyzed concentrations of EGF-family ligands in plasma and urine of rodents and human. For instance, it was shown that concentrations of EGF in serum of 60-day-old male mice ranged between 0.264 and 0.503 ng/ml (84); significant age and gender variability of EGF level was also noted by the authors. Considering the fact that ErbB receptors localize at the basolateral side and concentration in the lumen is at least 10-fold higher, these concentrations could represent the same range as levels required for ENaC modulation.

At least acute effects of EGF correlate with reactive oxygen species (ROS) production since pretreatment with the non-selective NADPH oxidase activity inhibitor apocynin blunted both generation of ROS and increase in ENaC-mediated current in response to EGF (48). Most likely, an increase in hydrogen peroxide (H2O2) levels mediates this effects since it was shown that H2O2 is critical for ENaC activity (23, 65, 69, 103). Furthermore, EGF had no effect in Rac1 knockdowned principal cells (48). It appears that small GTPase Rac1, which has been shown to be implicated in the development of many renal and cardiovascular diseases (54, 76, 95, 96), is a critical protein in transmission of the signal from EGF to ENaC. Rac1 might mediate its effects on ENaC either through the MAPK pathway (62, 100), WAVE proteins (52), or ROS production (48), since Rac1 is also one of the key subunits of the NADPH oxidase complex.

Role of EGF-EGFR Axis in the Development of Hypertension

A link between EGF-EGFR signaling pathway and renal vasculature and nephron functions was identified in several studies. Previous studies revealed that renal cortical expression of EGF was increased in both prehypertensive and hypertensive salt-sensitive (SS) rats (129). Immunohistochemical analysis demonstrated that EGF expression was increased in SS rats compared with Sprague-Dawley and Dahl/Rapp salt-resistant rats. Following addition of EGF, autophosphorylation of the EGFR was further enhanced in the primary cells derived from SS rats and this effect was especially strengthened in the renal vasculature (129). Previous EGF binding studies also revealed that SS rats (105) and the spontaneously hypertensive Lyon rats exhibited increased levels of EGFR in freshly prepared kidney and aortic tissue membranes compared with normotensive or hypertensive strains (106). Microarray-based global gene expression analysis in deoxycorticosterone acetate (DOCA)-salt-induced hypertensive rats further demonstrated that chronic treatment with an EGFR inhibitor AG1478 leads to inhibition of the majority of genes associated with development of renal dysfunction and hypertension in this model (5). Thus expression of EGF is associated with hypertensive pathology and can potentially play a role in kidney damage associated with high blood pressure. However, it is hard to define whether changes in gene/protein expression are a consequence of hypertension or the primary basis of the diseases. Previous excellent review by Cowley and Roman (19) discussed potential lines of evidence, which could help to evaluate...
this question. Additional studies are required for better understanding of the mechanisms resulting in development of hypertension, including salt-sensitive hypertension.

Several possible mechanisms may account for the role of ErbB signaling in the development of hypertension (4). EGF induces constriction of both preglomerular and postglomerular arterioles, resulting in acute major reductions in the rates of glomerular filtration and perfusion (40). EGF and TGF were described as vasoconstrictors on endothelium-denuded thoracic aortas dissected from two models of hypertension: 1) DOCA-salt; and 2) one-kidney, one-clip hypertensive rats (32). HB-EGF was also characterized as a vasoconstrictor released under influence of GPCRs, such as adrenceptors and angiotensin receptors, in isolated mesenteric arteries (38). Similarly, HB-EGF is required for endothelin-1-induced vasoconstriction and increase in blood pressure (14). Transactivation of EGFRs by GPCRs was also shown in the thoracic aorta smooth muscle cell line (24) and rat aorta (115). Moreover, it was shown that ANG II-induced hypertension and hypertrophy are attenuated by EGFR antisense (50). Briefly, a number of lines of evidence suggest that EGF-EGFR signaling mediates vasoconstriction and arterial hypertension in response to various stimuli. However, most of the studies of the role of EGF-EGFR axis in the vasculature are performed in the heart and conduit vessels and outside of the focus of current review.

As discussed above, in the collecting ducts EGF has a biphasic effect on ENaC-mediated sodium reabsorption. While acute changes to ErbB ligands are critical for the fast regulation of channel activity in response to alterations in cells environment under certain pathological conditions, chronic inhibition of ENaC is relevant to changes in the blood pressure and development of hypertension. Our recent data indicate that ENaC contributes to the development of hypertension in the Dahl SS rat strain (82), which is a commonly used model for the studies of salt-sensitive hypertension (20, 21, 28, 45, 132). Although a high-salt diet was found to downregulate ENaC in salt-resistant animals (33, 86), it was previously demonstrated that ENaC expression is upregulated in SS rats (1–3, 51). Our studies provide evidence that ENaC is abnormally regulated by dietary sodium in SS hypertensive rats, and this abnormal activity is one of the major factors causing salt-sensitive hypertension. Thus, as we recently demonstrated, ENaC activity is significantly enhanced in SS rats fed a high-salt diet compared with salt-resistant SS.13BN consomic strain and SS rats fed a low-salt diet (82). Importantly, the servo-controlled approach, which allowed us to determine the contribution of renal perfusion pressure (RPP) in the development of hypertension and renal injury in SS rats, provides evidence that ENaC is essential for the development of salt-sensitive hypertension. In the servo-controlled studies, the system maintains the RPP to the left kidney of the instrumented SS rat at control level, whereas RPP to the right kidney increases in response to a high-salt diet. Therefore, both left and right kidneys are exposed to an identical systemic neurohormonal and metabolic environment, but controlled levels of RPP within the left kidney protected it from the high pressure. At least, β-ENaC expression (as analyzed by immunohistochemistry) was increased in the uncontrolled kidneys compared with controlled left kidneys (82).

Our recent studies identified EGF as a key molecular substrate for a new positive feedback mechanism that diminishes development of salt-sensitive hypertension (82). First, we found that EGF concentration in the kidney cortex of SS rats fed a high-salt diet was significantly lower compared with SS rats on a low-salt diet or salt-resistant SS.13BN consomic rats fed a low-salt diet (82). on both diets (82), which is consistent with upregulation of EGFR expression (105, 129). To directly evaluate the role of EGFR in the development of hypertension and its effect on ENaC activity, EGFR was intravenously infused and blood pressure was continuously monitored. In addition, ENaC activity was assessed at the end of experiments, when EGFR was continuously infused during several days. Infusion of EGFR decreased ENaC activity, prevented the development of hypertension and attenuated renal glomerular and tubular damage (82). As shown on Fig. 4, in vivo EGF infusion prevents development of salt-induced hypertension (Fig. 4A) in this strain and decreases ENaC activity in collecting ducts, which might mediate EGF effects on blood pressure (Fig. 4, B and C). We believe that these findings advance our understanding of salt-sensitive hypertension and provide some insight into its molecular basis (Fig. 5). Importantly, recent studies in mice demonstrated that the EGFR monoclonal antibody Cetuximab given intraperitoneally for 8–10 days raised the blood pressure of mice on normal-salt diet by 25 mmHg and that of those on high-salt diets by 34 mmHg (85). The authors proposed that downregulation of ENaC by arachidonic acid metabolites (83, 84) mediates these effects (85). Thus it appears that EGF-EGF signaling is involved in blood pressure regulation not only in salt-sensitive but also in salt-resistant animals.

Conclusion

ErB family members are implicated in the development of cancer and cardiac and renal diseases such as AKI, CKD, PKD, and hypertension. Therefore, the therapeutic potential of targeting the ErbB receptors and EGFR-family signaling pathways needs further detailed investigations. Undoubtedly, many questions remain regarding regulation of sodium reabsorption and hypertension by ErbB ligands. For instance, receptor specificity plays the key role in these mechanisms. Furthermore, it is not clear if different ligands targeting the same homo- or heteromer work as a complex and whether they have different affinities and different efficacies depending on the target conformation. Also, transactivation of ErbB receptors and the crucial roles of ADAM and MMP proteases are understudied. In addition, we would like to emphasize that special caution needs further detailed investigations. Undoubtedly, many questions remain regarding regulation of sodium reabsorption and hypertension by ErbB receptors and EGF-family signaling pathways and the therapeutic potential of targeting the ErbB receptors and EGF-family signaling pathways in DOCA-salt-induced hypertensive rats occurs via signaling cascades involving epidermal growth factor receptor: a microarray analysis.
