Renal ischemia-reperfusion induces a dysbalance of angiopoietins, accompanied by proliferation of pericytes and fibrosis. Am J Physiol Renal Physiol 305:F901–F910, 2013. First published July 3, 2013; doi:10.1152/ajprenal.00542.2012.—Endothelial cells (ECs) are highly susceptible to hypoxia and easily affected upon ischemia-reperfusion (I/R) during renal transplantation. Pericytes and angiopoietins play an important role in modulating EC function. In the present study, we investigate the effect of renal I/R on the dynamics of angiopoietin expression and its association with pericytes and fibrosis development. Male Lewis rats were subjected to unilateral renal ischemia for 45 min followed by removal of the contralateral kidney. Rats were killed at different time points after reperfusion. Endothelial integrity (RECA-1), pericytes [platelet-derived growth factor receptor-β (PDGFR-β)], angiopoietin-2 (Ang-2)/angiopoietin-1 (Ang-1) expression, and interstitial collagen deposition (Sirius red and α-smooth muscle actin) were assessed using immunohistochemistry and RT-PCR. Our study shows an increase in protein expression of Ang-2 starting at 5 h and remaining elevated up to 72 h, with a consequently higher Ang-2/Ang-1 ratio after renal I/R (P < 0.05 at 48 h). This was accompanied by an increase in protein expression of the pericyte marker PDGFR-β and a loss of ECs (both at 72 h after I/R, P < 0.05). Nine weeks after I/R, when renal function was restored, we observed normalization of the Ang-2/Ang-1 ratio and PDGFR-β expression and increase in cortical ECs, which was accompanied by fibrosis. Renal I/R induces a dysbalance of Ang-2/Ang-1 accompanied by proliferation of pericytes, EC loss, and development of fibrosis. The Ang-2/Ang-1 balance was reversed to baseline at 9 wk after renal I/R, which coincided with restoration of cortical ECs and pericytes. Our findings suggest that angiopoietins and pericytes play an important role in renal microvascular remodeling and development of fibrosis.

angiopoietins; renal ischemia/reperfusion injury; pericytes; microvascular damage

RENAL ISCHEMIA-REPERFUSION (I/R) is an inevitable consequence of renal transplantation causing significant graft injury (5, 16, 29). Renal I/R impairs the integrity of endothelial cells (ECs) and leads to loss of peritubular capillaries (6, 9, 17, 19, 25, 32, 36). Loss of integrity and function of the endothelial monolayer lead to renal hypoxia, which is suggested to be a major initiator of profibrotic changes and interstitial scar formation in the kidney (2, 24). These microvascular changes and renal scarring eventually lead to deterioration of renal function and graft loss (26).

Pericytes play a critical role in the stabilization and proliferation of peritubular capillaries via interaction with ECs (1, 20, 30). This process is mediated by several angioregulatory factors, including angiopoietin (Ang)-1, produced by pericytes, and Ang-2, produced by activated ECs (7, 30, 35). Angiopoietins are a group of vascular regulatory molecules that bind to the receptor tyrosine kinase Tie-2, which is predominantly expressed by vascular ECs. Ang-1 is a strong vascular protective agonist of the Tie-2 receptor responsible for suppressing vascular leakage, maintaining EC survival, and inhibiting vascular inflammation. Ang-2 acts as an antagonist of Ang-1 and in a dose-dependent manner promotes destabilization, vessel leakage, and inflammation. By promoting pericyte dropout, Ang-2 will lead to loosening contacts between ECs and perivascular cells, with subsequent vessel destabilization and abnormal microvascular remodeling (7, 14, 15, 35). Recent studies have shown that pericytes detach from the endothelium and migrate to the interstitium to become activated and differentiate into myofibroblasts contributing to renal fibrosis (10, 12). Interestingly, treatment with cartilage oligomeric matrix protein (COMP)-Ang-1 in a mice model of renal I/R injury resulted in protection against peritubular capillary damage and a decrease in inflammatory cells and renal interstitial fibrosis (19).

However, dynamics and the time course of angiopoietin expression and its relation with EC and pericycle expression and development of fibrosis in the repair phase after renal I/R injury are unknown. Using an established rat model of renal I/R injury, we assessed the impact of I/R on Ang-2/Ang-1 balance and its effect on microvascular remodeling, pericytes, and the formation of fibrosis up to 9 wk after renal I/R injury. We hypothesize that I/R injury leads to activation of ECs with consequent elevation of Ang-2 levels, which may lead to proliferation of pericytes and loss of ECs but may also induce fibrosis in the long term.

MATERIALS AND METHODS

Rat model of renal I/R injury. Renal I/R injury was induced as previously described (34). The Animal Care and Use Committee of the Leiden University Medical Center approved all experiments. Eight-week-old male Lewis rats (200–250 g) purchased from Harlan (Horst, The Netherlands) were housed in standard laboratory cages and allowed free access to food and water throughout the experiments.
Unilateral ischemia was induced by clamping of the left renal pedicle for 45 min using a bulldog clamp (Fine Science Tools, Heidelberg, Germany). During clamping the contralateral kidney was removed. Sham-treated rats had identical surgical procedures except for clamping of the left kidney. Tail blood samples were taken before and at indicated time points after reperfusion and were kept on ice. Rats were killed at 2, 5, 24, 48, or 72 h (h) and 1, 6, and 9 wk (wk) after reperfusion, and kidneys were harvested for histological examination and immunohistochemical staining. Renal function was assessed by measuring creatinine and urea (BUN) in serum samples using standard auto analyzer methods by our hospital research services.

**Histologic evaluation.** Renal fibrosis was evaluated histologically by Sirius red staining as described previously (27) on 4-μm paraffin slides of renal rat tissue. From each part of the kidney (cortex and outer and inner medulla), five random images were obtained. Image analyses was performed using ImageJ software. The amount of collagen deposition was measured and expressed as percentage of positivity per region of the kidney. In addition, all tissue specimens were scored for severity of fibrosis on a semiquantitative scale (0–3) in a blinded manner by an experiences pathologist.

**RNA isolation and real-time PCR.** RT-PCR was performed as described previously (34). Total RNA was extracted from snap-frozen cross-section kidney slices using the RNeasy Mini isolation kit according to the manufacturer’s instructions (Qiagen, Hilden, Germany). cDNA was synthesized from 1 μg total RNA, using an oligo dT primer, RNase-out, MMLV reverse transcriptase, 0.1 M-DTTI, and buffers in a volume of 20 μl (all purchased from Invitrogen, Breda, The Netherlands). Quantitative real-time PCR was performed in duplicate by using iQ SYBR Green Supermix on iCycler Real-Time Detection System (Bio-Rad). The amplification reaction volume was 20 μl, consisting of 10 μl iQ SYBR Green PCR mastermix, 1 μl primers, 1 μl cDNA, and 8 μl water. Data were analyzed using Gene Expression Analysis for iCycler Real-Time PCR Detection System (Bio-Rad). Expression of each gene was normalized against mRNA expression of the housekeeping gene Rsp-15. RT-PCRs were performed in duplicate. The primer sequences are shown in Table 1.

**RESULTS.**

Renal I/R induces transient deterioration of renal function, influx of inflammatory cells, and interstitial fibrosis. In the current study we used a rat model of renal I/R resulting in extensive renal dysfunction, as shown by increased serum creatinine and BUN levels, but characterized by normalized renal function after 1 wk following I/R ($P<0.05$, compared with 72 h; Fig. 1, A and B). Renal dysfunction was accompanied by significant infiltration of OX42$^+$ inflammatory cells in the cortex and outer and inner medulla at 72 h ($P<0.05$), which peaked at 1 wk compared with sham-operated rats (Fig. 1, E–G). A decrease in OX42$^+$ inflammatory cells was observed at 6 and 9 wk in the different parts of the kidney compared with 1 wk following I/R ($P<0.05$). In the outer and inner medulla, the influx of OX42$^+$ cells remained significantly increased up to 6 and 9 wk ($P<0.05$), respectively, after renal I/R injury compared with sham-operated rats (Fig. 1G). Consistently, CD45 expression in the cortex showed a similar pattern as OX42$^+$ staining (Fig. 1, C and D).

One week after reperfusion, significant diffuse interstitial collagen deposition was observed in the cortex, outer and inner medulla compared with sham-operated rats ($P<0.05$) (Fig. 2, A and B). After 9 wk, collagen deposition was significantly decreased in different regions of the kidney compared with 1

wk following renal I/R injury \((P < 0.05)\), although kidneys were still characterized by focal areas of intense Sirius red staining. The semiquantitative analyses showed that fibrosis scores at 9 wk were not statistically different from 1 wk after I/R (data not shown), which is probably due to the focal areas of fibrosis. Consistently, the \(\alpha\)-SMA immunohistochemical staining revealed a significant increase of fibrosis in cortex and outer medulla at 72 h \((P < 0.05)\) and at all parts of the kidney at 1 wk \((P < 0.05)\) following I/R injury compared with sham-operated rats (Fig. 2, C and D). At 9 wk, \(\alpha\)-SMA staining

Fig. 1. Renal ischemia-reperfusion (I/R) induces deterioration of renal function and influx of inflammatory cell. Serum creatinine levels (A) and blood urea nitrogen (BUN; B) were measured at consecutive time points after reperfusion. CD45-positive leukocyte infiltrate was quantified using digital image analysis (C). Representative photomicrographs of kidney sections stained with CD45 (D) from a sham-operated rat and a rat subjected to I/R and killed at 72 h after reperfusion. An overview of the division of the different regions [cortex (C) and outer medulla (OM) and inner medulla (IM)] in a kidney section stained with OX42 (E). Representative photomicrographs of kidney sections stained with OX42* from a sham-operated rat and rats subjected to I/R and killed at 72 h or 9 wk after reperfusion (F). OX42* infiltrate of sham-operated rats and rats subjected to I/R was quantified in the different areas using digital image analysis (G) and demonstrated as percentage of the depicted area. Data are shown as means ± SE \((n = 5\) rats per group). \(*P < 0.05,\) compared with corresponding sham controls. \#\(P < 0.05,\) compared with 72-h or 1-wk rats. Restoration of peritubular capillaries in the cortex 9 wk after renal I/R. Since endothelial damage is an important hallmark of I/R injury, we assessed peritubular capillaries over time by staining for RECA-1. A significant reduction in RECA-1 expression was observed at 72 h post-I/R (P < 0.05) in the cortex (P < 0.05) compared with sham-operated rats (Fig. 3, A–C). Interestingly, we found a significant increase of RECA-1 staining at 6 and 9 wk in the cortex (P < 0.05) following I/R compared with rats that were killed at 72 h (Fig. 3B). Calculation of the ratio I/R-injured/sham-operated rats for RECA-1 expression confirmed the observed increase at 6 and 9 wk after injury (Fig. 3B). RECA-1 staining colocalized with the proliferation marker Ki-67, suggesting EC proliferation in peritubular capillaries within the renal cortex at 9 wk after I/R (Fig. 3, D and E). No proliferation of ECs was found in the glomeruli following renal I/R. In the outer and inner medulla,
a different pattern was found. Here a significant reduction in RECA-1 expression was observed at 72 h post-I/R in the outer medulla ($P < 0.05$) and at 1 wk in the inner medulla ($P < 0.05$) compared with sham-operated rats (Fig. 3C). In contrast to the cortex, RECA-1 staining in these areas showed a further decrease up to 9 wk after ischemic injury ($P < 0.05$; Fig. 3C). CD31 staining demonstrated a pattern comparable to the RECA-staining (Fig. 3F).

Renal I/R induces a dysbalance in Ang-2/Ang-1 ratio at early time points and return to baseline after 6 wk. In control kidneys of sham-operated rats, Ang-1 staining was observed in the glomeruli and in a capillary like pattern between the tubuli
to 72 h in the cortex and up to 9 wk in both the outer and inner pericytes was observed at 48 h upon I/R in all parts of the peritubular capillaries (Fig. 5). A significant increase of cells in the mesangium, Bowman’s capsule, large vessels, and H9252 (Fig. 4) operated group and reversal to baseline levels at 9 wk after I/R showed a significant decrease at 1 wk compared with sham-operated rats (Fig. 4).

In control rats, low levels of Ang-2 protein were observed in glomeruli, interstitial vessels and on brush borders of tubuli (Fig. 4, B and G). Due to the apical and brush border expression on tubuli of Ang-2 in the medulla, it was technically not possible to distinguish between interstitial and tubular presence of Ang-2 (Fig. 4E). Therefore, quantification of angiopoietins was only performed in the cortex. Additional double staining of Ang-2 and RECA-1 confirmed the expression of Ang-2 by ECs (Fig. 4D). Compared with sham-operated rats, Ang-2 expression increased at 5 h (data not shown) and remained elevated up to 72 h (P < 0.05) after I/R (Fig. 4G). Consequently higher Ang-2/Ang-1 ratios were observed after 48 h and 72 h (P < 0.05; Fig. 4H). After 1 wk, Ang-2 levels and Ang-2/Ang-1 ratio started to decrease, reaching significance at 6 and 9 wk compared with 72 h after renal I/R (Fig. 4, B, G, and H). Ang-2 mRNA levels did not confirm the observed changes at protein levels (Fig. 4J). Tie-2 mRNA expression showed a significant decrease at 1 wk compared with sham-operated group and reversal to baseline levels at 9 wk after I/R (Fig. 4K).

Renal I/R leads to proliferation of pericytes. Immunohistochemical staining revealed the presence of PDGFR-β positive cells in the mesangium, Bowman’s capsule, large vessels, and peritubular capillaries (Fig. 5A). A significant increase of pericytes was observed at 48 h upon I/R in all parts of the kidney compared with sham-operated rats, which persisted up to 72 h in the cortex and up to 9 wk in both the outer and inner medulla (P < 0.05) (Fig. 5, A and B). PDGFR-β expression showed normalization at the protein level in all regions of the kidney (P < 0.05) at 9 wk after renal I/R injury (Fig. 5, A and B). To investigate the anatomical relation of ECs and pericytes, double staining with RECA-1 and the pericyte marker NG2 was performed, which revealed expression of both markers in the glomeruli and peritubular space (Fig. 5C).

DISCUSSION

We performed a detailed kinetic analysis of angiopoietin and pericyte expression after renal I/R injury. We demonstrate that renal I/R induces a dysbalance in Ang-2/Ang-1, which is accompanied by a loss of ECs, proliferation of pericytes, and development of fibrosis. At 9 wk post-I/R, we show reversal to baseline in Ang-2/Ang-1 balance, an increase in ECs, and normalization of PDGFR-β expression in the cortex. Whereas renal function is fully restored at this time point, the renal tissue does still show signs of fibrosis.

It is postulated that loss of ECs is a central common pathway involved in organ failure that precedes and drives the profibrotic changes of the kidney parenchyma (2, 3, 24). Different reports using animal models have been published that demonstrate chronic deleterious effects of ischemic injury on long-term renal function and microvascular structure (2, 6, 16, 17, 29, 36). Basile et al. (2) have shown that renal I/R in a rat model results in permanent damage to peritubular capillaries with development of tubulointerstitial fibrosis and decline in long-term renal function. In the present study, we also observed loss of peritubular capillaries and development of tubulointerstitial fibrosis following renal I/R, which were more severe and extensive in the outer and inner medulla than the cortex. The observed fibrosis at early time points after renal I/R injury in our study coincided with the influx of inflammatory cells. At later time points, we observed a different pattern of fibrosis, which was more dense and unrelated to the areas of inflammation. This “inflammatory fibrosis” observed at early times has been reported to be important for restoration of the original tissue morphology and function (13). It is, however, also suggested that if repair is not efficient at early times, fibrosis at the repair phase cannot be prevented (9). In our study, at 9 wk after reperfusion, restoration and proliferation of ECs were found in the cortex but not in the outer and inner medulla. This could be caused by the anatomical relationship of capillaries and tubules in the outer and inner medulla, with consequently a greater impact of hypoxia- and leucocyte-induced EC damage than in the cortical peritubular capillaries (5).

In contrast to the study of Basile et al. (2), we found restoration and proliferation of ECs in the cortex in the repair phase (9 wk after I/R). Possible explanations for this discrepancy between our study and the studies of Basile could be differences in clamping time (45 vs. 60 min, respectively) and the removal of the healthy contralateral kidney in our study. In the study of Basile, additional experiments in which rats were subjected to 30 and 45 min of bilateral ischemia were performed to assess whether the duration of ischemic injury affects damage to the renal microvasculature and function. Both renal function and capillary density were more disturbed in the 45-min group compared with the 30 min rats, which might implicate a “critical ischemia time” for endothelial repair (2).

The molecular mechanisms that lead to microvascular injury in organ failure are largely unknown. It has been suggested that several angioregulatory growth factors, including the angiopoietins, play a central role in the loss of vascular integrity (18, 36). In this regard, a study has shown that treatment with COMP-Ang-1 (soluble, stable, and potent form of Ang-1) in a mouse model of renal I/R resulted in protection against peritubular capillary damage, decrease in interstitial inflammatory cells, and renal interstitial fibrosis (5). Other investigators have demonstrated stabilization of peritubular capillaries along with increased fibrosis and inflammation after adenosival Ang-1 treatment in a mouse model of folic acid-induced nephrotoxicity (37). These studies suggest that differences in efficacy of Ang-1 in the kidney may be due to variation in potency of Ang-1 and COMP-Ang-1 or difference in kidney disease models (5, 12, 37). Ang-2 acts as an antagonist of Ang-1 and increases vessel leakage, inflammation, and destabilization by promoting pericyte loss, therefore, loosening contacts between ECs and pericytes (18, 36).

An interesting observation in this study is that we found a relation in time between Ang-2/Ang-1 balance and microvascular integrity and pericytes in the cortex after I/R. Activation

ECs, reflected by increase in Ang-2 expression and consequently higher Ang-2/Ang-1 ratio, was accompanied by proliferation of pericytes, EC loss, and development of fibrosis. This relation between EC loss and dysbalance in angiopoietins has also been demonstrated in a mouse model of antiglomerular basement membrane glomerulonephritis, where glomerular capillary loss was associated with reduced Ang-1 and increased Ang-2 expression (38). In addition, in an animal model of diabetic retinopathy, Ang-1 was shown to have a profound effect in repairing integrity of the retinal EC permeability barrier (39). Moreover, injection of Ang-2 into the eyes of normal rats has been shown to induce a dose-dependent pericyte loss (28). These findings suggest an important role for the angiopoietins in generating a proangiogenic environment that is necessary for capillary repair.

Several studies have pointed at the critical importance of the interaction between pericytes and ECs in maintenance of the capillary network (1, 30). Surprisingly, hardly any data are available on the relation between pericytes and loss of ECs in renal I/R. Only one study has shown an association between damage to peritubular capillaries and decreased number of pericytes in cadaveric renal allografts after I/R (21). Peritubular capillary integrity was better preserved and pericytes were more pronounced in patients who had a better recovery of their graft function compared with patients with sustained postischemic acute kidney injury (21). However, this study investigated the expression of pericytes at only one time point early after renal I/R and did not investigate the relation to angiopoietins and development of fibrosis in a time course.

To investigate the role of pericytes in renal I/R injury, we used PDGFR-β as pericyte marker. PDGFR-β is a single-spanning transmembrane glycoprotein that binds to its dimeric ligand PDGF and a crucial receptor for recruitment and survival of pericytes by paracrine secretion of PDGFR-β by ECs (4, 23, 33). PDGFR-β has been shown in studies of obstructive and postischemic kidney injury to be expressed by pericytes and fibroblasts (8, 22, 23). Compared with other pericyte markers, PDGFR-β continued to be expressed after proliferation of pericytes and after transformation into myofibroblasts (11, 18, 23, 30). Recently, Duffield and colleagues (11, 18, 23, 30) provided evidence for the contribution of pericytes to the development of renal fibrosis. With the use of a transgenic mouse model of unilateral ureter obstruction (UOO), expressing green fluorescent protein in cells producing the collagen...
type I, they demonstrated that pericytes are the main source for interstitial myofibroblasts during renal fibrosis (23). The same investigators showed migration of perivascular stromal cells from capillaries into the renal interstitium, within 9 h after induction of ureter obstruction. After loosening contact from the capillaries, pericytes became activated and proliferated into collagen producing myofibroblasts contributing to fibrosis (23). PDGFR-β signaling has been reported to play an important role in the development of fibrosis. Blockade of PDGFR-β attenuated recruitment of inflammatory cells, loss of ECs and fibrosis in mice subjected to renal I/R injury and UUO (22). Also in our study we demonstrated proliferation of pericytes and loss of ECs, which was accompanied by development of fibrosis. The pericytes may have responded to injury by detaching from the capillaries and becoming pathologic matrix-depositing cells that contribute to the population of α-SMA-positive cells in the fibrotic interstitial space observed in this study (8, 31). The process of pericyte detachment has been suggested to be reversible, which could explain the observed decrease in PDGFR-β expression and the restoration of ECs in the cortex (22). However, in both the inner and outer medulla an increase of PDGFR-β cells was observed up to 9 wk after renal I/R. Interestingly, these areas had no increase in EC staining and demonstrated a more profound fibrosis reaction compared with the less damaged cortex area.

An important discussion point remains whether the decrease in RECA-1 in the cortex observed in our study is explained by EC loss or by interstitial edema and compression of peritubular capillaries. However, previous studies utilizing microfilm analysis and EC staining with CD31 confirmed the loss of ECs after I/R (2, 3, 17, 19, 32). Additional CD31 staining in this study revealed a similar pattern as observed with RECA-1. Although our study clearly suggests that angiopoietins are essential in renal microvascular remodeling in the cortex, we were not able to analyze the outer and inner medulla of Ang-2 staining. Ang-2 showed brush border and apical expression on tubules in the medulla, making it difficult to distinguish between interstitial and tubular presence of Ang-2. Therefore, we focused only on the cortex for angiopoietins staining. Furthermore, we observed a discrepancy in Ang-2 protein and mRNA expression, which could be explained by the use of whole kidney RNA extractions instead of a specific region as for immunohistochemistry or contribution of earlier produced Ang-2 by infiltrating cells, while lacking the detectable transcript (28). A therapeutic intervention would be required to prove a causal relationship between the functions of angiopoietins and pericytes and its role in EC stabilization and repair.

In conclusion, our study demonstrates that renal I/R induces a dysbalance in angiopoietins, accompanied by proliferation of pericytes and development of fibrosis. These findings support the hypothesis that angiopoietins and pericytes play an important role in renal microvascular remodeling. Since angiopoietins and pericytes are considered as important hallmarks of microvascular integrity, strategies to counteract microvascular destabilization after I/R may well improve long-term graft function.
